EXPLOSIONS IN COAL-MINES

Explosions in Coal-Mines. By W. N. and J. B. Atkinson, H.M. Inspectors of Mines. (London: Longmans, 1886.)

EVERYBODY in the least degree conversant with matters connected with coal-mining will at once admit that our knowledge of the remote causes of colliery explosions has increased enormously during the last few years. Whether, however, the practical application of this knowledge has kept pace with the rate of increase in the knowledge itself is another matter. Since 1851, when the first Mines Inspection Act was in force, the number of fatal explosions in collieries has steadily diminished, but the annual loss of life from these catastrophes is as great as ever. During the ten years ending 1860 there were 820 fatal explosions, resulting in 2441 deaths, or an average of 2·98 deaths per fatal explosion; during this decade there was an average of 3000 persons employed in and about the mines for every fatal explosion, and 1008 persons for each resulting death. During the ten years ending 1870 the number of fatal explosions fell to 565; the deaths were 2267, or an average of 4·01 per fatal explosion; and the ratio of persons employed to each fatal explosion was 5650, and hence to each resulting death 1408. During the ten years ending 1880 the number of fatal explosions was 424; the resulting deaths were 2686, or an average of 6·33 per fatal explosion; the ratio of persons employed to each fatal explosion was 11,372, and to each resulting death 1795. During the five years ending 1885 we have had 146 fatal explosions, with a loss of 906 persons, or an average of 6·20 deaths from each explosion; the ratio of persons employed to each fatal explosion was 17,503, and to each resulting death 2820. These figures are in the highest degree significant, but they are not capable of telling everything. They do not, for example, bring out the fact that the actual violence of colliery explosions when they do occur is nowadays greater than formerly. This may seem to be indicated by the increase in the average number of deaths from each fatal explosion, but then, on the other hand, there are far more men employed in pits now than formerly. The diminished number of explosions is probably due, in the first instance, to the more general employment of safety-lamps, and, during late years, to the restrictions which have been placed upon the use of explosives. The increase in the average number of deaths to each explosion is doubtless owing to the gradual deepening of the pits and to differences in the mode of origin and character of the explosion. Thirty years ago the pits as a rule were comparatively shallow and damp. Such a sinking as that of the Ashton Moss pit at Audenshaw, which is upwards of half a mile deep, was unknown. Explosions in these damp shallow pits were usually caused by the ignition of gas, most frequently by naked lights; they were very local in their action, and the loss of life was small. Nowadays an explosion in a deep and dry mine not unfrequently penetrates throughout the whole pit; it is often extremely violent, and the number of deaths, mainly from after-damp, is correspondingly great.

There can be very little doubt that such explosions are, in the main, caused by dust. The fact that fire-damp is not the only explosive agent which may be present in coal-mines is now generally recognised. It is, however, a moot point with many practical men whether coal-dust alone, in the entire absence of gas, can bring about an explosion of any magnitude. It is generally conceded that a very small amount of gas, an amount, indeed, too small to be recognised by the elongation of the flame of a safety-lamp, or the formation of a "cap," is sufficient in the presence of coal-dust to form a dangerously explosive atmosphere, but colliery managers and many mining engineers have, apparently, been slow to believe that dust itself may, under certain conditions, effect an explosion quite as violent in its character as the most formidable gas explosion of which we have any record. The Royal Commissioners appointed to inquire into accidents in mines reported that in their opinion it was well established that even when the air is quite free from fire-damp, an exceptionally inflammable coal-dust, in a very finely-divided and dry condition, and existing in abundance in the immediate vicinity of a blown-out shot, may when raised by the shot be ignited so readily and carry on the flame so rapidly that it may produce explosive effects of a similar character to those caused by a gas explosion. The flame as it rushes along, if fed by freshly raised dust, may extend under these circumstances to very considerable distances, with results resembling, in their disastrous nature, those of explosions originating with, and mainly due to, fire-damp. This conclusion is very greatly strengthened by the evidence which the Messrs. Atkinson have brought together in the book before us. Their work indeed constitutes the most formidable indictment against coal-dust as a cause of colliery explosions which has yet been drawn up. In their capacity of Inspectors they have investigated with the most patient care the circumstances connected with what we may call six typical explosions. These were—

Date	Name of colliery	Deaths	Time of explosion	Seams affected
[illegible]				
Sept. 8	Seaham	164	2.20 a.m.	Maudlin and Hutton
1882				
Feb. 16	Trimdon Grange	74	2.30 p.m.	Harvey
April 18	Tudhoe	37	1.15 a.m.	Brockwell
April 19	West Stanley	13	1.0 a.m.	Basty
April 25	Whitehaven	4	11.15 p.m.	Main Band
1885				
March 2	Usworth	42	8.58 p.m.	Maudlin

All the explosions with the exception of that at Whitehaven were in the county of Durham. It would be quite impossible in the space at our disposal to follow the successive steps in the minute analysis to which the authors have subjected each of these explosions. We should require, moreover, many of the numerous plans of the colliery workings with which the book is illustrated were we to attempt such a task. All that can now be done is to point out the characteristic features of the several explosions, and to indicate the general conclusions which the authors draw from the consideration of the various circumstances connected with them. We are conscious that in some respects this method of treating their work hardly does justice to the authors. It fails to convey any idea of the thoroughly scientific manner in which the Messrs. Atkinson's investigations have been conducted; of the minute and painstaking mode of their observation; or of the care and skill with which their deductions have been made. The authors, even in the earlier pages of the book, make their position in regard to the question of Gas *versus* Dust perfectly clear, but not even the most prejudiced opponent of the dust hypothesis can complain of the manner in which the evidence is presented.

The Durham explosions presented many features in common. In the first place no accumulations of gas were known to exist in quantity sufficient to cause the widespread destruction which happened, nor were such accumulations considered possible. In all these explosions the downcast shafts were more or less damaged. At Trimdon Grange, Tudhoe, West Stanley, and Usworth the explosions did not cross the downcast shafts; these were wet, and the roadways near them were damp. At Seaham the shaft was dry, and the explosion crossed it and extended far beyond it. In all cases the violence and ame of the explosions were confined to roads on which there was much coal-dust. The explosions were most violent in the intake and haulage roads, or between the downcast shafts and lamp-stations, *i.e.* in places where practically no gas was to be expected, and where naked lights were in constant use. The path of the explosion was in all cases that of the fresh air traversing the pit: in no case did it extend by means of the return air-way The return air-ways carry off the gases evolved in the pit, but are practically free from dust. In certain of the intake air-ways at Seaham and Usworth no coals were led, and they were consequently comparatively free from coal-dust: no traces of the explosions were observed in these roads. The explosions were in many cases arrested where the haulage roads were wet. In no instance did the explosion ascend or descend vertically through staples or shafts communicating with other planes of workings. If the explosions were due to gas, their extension would not be influenced by the direction of a communicating passage; on the other hand, very little coal-dust collects in vertical passages. In almost every case of an explosion which could with certainty be attributed to fire-damp, there is evidence that men have been alarmed and have attempted to escape from the workings before the actual occurrence of the disaster: in all the five Durham explosions there was no indication that any movements had taken place amongst the men suggestive of alarm; their bodies were found in the places where their work required them to be, close to their tools and lamps.

At Seaham, Tudhoe, West Stanley, and Usworth the explosions were simultaneous with the firing of shots in stone; in these cases the explosions occurred when the pits were occupied by stonemen and repairers and at the only time when the operations of the mines allowed the firing of shots. At Seaham, Tudhoe, and Usworth the shots were fired on a main intake air-road and at points where currents of air of between 20,000 and 30,000 cubic feet per minute were passing. At West Stanley the shot was fired, in stone, at a working place by a naked flame, and the air in the vicinity would probably contain a small quantity of fire-damp, but not sufficient in amount to show its presence in the safety-lamp or by itself to be explosive. In the other cases it is almost impossible to conceive that the air could contain any sensible quantity of gas. At Seaham it would be necessary to assume that the gas came down the shaft, or that there were three separate and simultaneous outbursts of it on the three main roads diverging from the shaft. At Tudhoe, where the air came direct from the surface by two shafts, it would be necessary to assume two separate and simultaneous outbursts. At Usworth the air had passed no working place, and could hardly have contained even a trace of fire-damp. At West Stanley no appreciable quantity of gas could be present in the main intakes, although a small quantity might be contained in the air near the place where the shot was fired.

There remains the Trimdon Grange explosion, which, was unconnected with shot-firing. There was distinct evidence that it originated with the ignition of gas at the light of a boy engaged at a pump in connection with some drowned workings from which gas was found to issue and that it extended with great force to parts of the pit more than a mile distant from its origin along the main intake air-ways.

Now all the circumstances connected with the Durham disasters make it almost certain that the main agent in the propagation of the explosion was dust, and in three out of the five cases it was dust alone. In four out of the five cases the immediate cause was shot-firing, *but in no instance was the shot blown out*. It is not at all necessary that the shot should be blown out to cause the ignition of the dust-cloud which the concussion raises in a dusty road. Properly fired shots show flame even when they dislodge the stone or coal; and the flame is often considerable if there has been an overcharge of powder, or if small coal or earth mixed with coal-dust has been used, as frequently happens, in the tamping. At Seaham, Tudhoe, West Stanley, and Usworth the flame of the shot ignited the dry inflammable dust dislodged from the roof or raised from the floor by the concussion of air which followed, and the explosion was propagated by fresh dust-clouds raised in the manner described by the Royal Commissioners. At Trimdon Grange an explosion of fire-damp operated in the same way: the violent movement of air resulting from the ignition of fire-damp and air raised a cloud of coal-dust into which the flame from the fire-damp passed, and the ignition of the coal-dust propagated itself as in the other cases, and, as in these, continued so long as it was fed by fresh fuel. This rapid ignition of dust containing upwards of 80 per cent. of carbon would result in the formation of large quantities of carbonic acid, and possibly even of the more poisonous carbonic oxide: when it is considered that it is impossible to live in air containing even $3\frac{1}{2}$ per cent. of carbonic acid, the deadly character of the after-damp so formed is readily conceivable.

In striking contrast to the Durham explosions was that at Whitehaven. This was in a wet pit; the coal being worked was wet, and all the surroundings were damp, and free from dust. The cause of the explosion was gas, which was known to be in the pit, and frequently present in large quantities. Although it is probable that some 30,000 cubic feet of an inflammable mixture of air and fire-damp were ignited, the explosion was confined to a limited area of the workings, which extend to nearly three miles from the shafts. Seven men were within the district of the explosion, of whom three escaped. The survivors stated that all the men were alarmed by the appearance of gas immediately before the explosion, and hurried away. In the act of retreating the gas ignited at a lamp which was afterwards proved to have been defective and to allow of the passage of the flame. This the authors say was the most considerable explosion of fire-damp and air that they are acquainted with. They have personally investigated during the last twelve years almost all the explosions occurring in the North of England, and they cannot point to a case where there was direct evidence of so large a quantity of fire-damp and air exploding.

The moral of all this is obvious. It can scarcely be gainsaid that some of the most disastrous explosions of the last thirty years are primarily to be attributed to the practice of firing gunpowder in dusty mines. That under certain circumstances gunpowder can be used with safety is allowed. But the Royal Commissioners have issued a warning in no uncertain terms. They have convinced themselves that the abolition of the use of powder in dry and dusty mines will not generally involve any formidable inconvenience, inasmuch as the work which is accomplished by its employment both in coal and in stone can now be performed with equal efficiency, and at very little if any greater outlay, by other means. Unless, therefore, mining engineers, or those immediately responsible for the working of collieries, can devise some satisfactory method of minimising the danger due to dust, they will be compelled before very long, in deference to public opinion, to renounce the practice of blasting by means of gunpowder, or by any other agent which causes a flame.

T. E. THORPE

McLENNAN'S "STUDIES IN ANCIENT HISTORY"

Studies in Ancient History: comprising a Reprint of "Primitive Marriage." By the late John Ferguson McLennan. A New Edition. (London: Macmillan and Co, 1886.)

THE first edition of "Primitive Marriage" appeared in 1865, and the book was already extremely rare when, in 1876, it was reprinted as the first part of the "Studies in Ancient History." The reprint also soon became scarce, and while the influence of the author has been steadily growing, and almost all students of early society have come to attach great importance to his speculations, his principal writings have for some years been almost inaccessible. This new edition therefore supplies a real want, and it is doubly welcome for the sparing, but judicious, notes and appendixes which the editor, Mr. D. McLennan, has attached to his brother's book. "Primitive Marriage" broke ground in a new field of research, and, as the point of view was wholly novel, the collection, sifting, and marshalling of the evidence on which the argument was based was entirely pioneer's work. At the close of his life, McLennan was in possession of a much larger material; he had pursued his argument in new directions and to further conclusions, and on one or two points he had come to change his views. But new research had only confirmed the main lines of the argument sketched with so firm a hand in his original essay; and read with the *caveats* which his brother has introduced at one or two points—chiefly as regards the interpretation of the Levirate, and the prevalence of Agnation—the present reprint may be taken as generally representing, so far as it goes, the author's final conclusions on the subjects discussed. I say *so far as it goes*, for in many directions his conclusions had been added to and his views developed. The editor promises us a second volume, to consist for the most part of writings hitherto unpublished, which will throw a good deal of light on these new developments; meanwhile he has restricted himself in the notes "to certain matters on which the author had announced a change of view, and to certain others where circumstances had made an additional statement imperative." Of the additional statements, the most important is contained in two long notes appended to the essay on Morgan's "classificatory system" of relationships, in which it is clearly made out that Morgan's theory rests on misconception of the facts, and that the supposed classificatory system of relationship is not a system of relationship at all, but a system of terms of ceremonial or friendly address, used in conversation even between persons who are not related to one another in any way. This comes out so clearly in the cases about which we are best informed, that it is very questionable whether the facts so laboriously collected by Mr. Morgan can be used to throw light on the early history of the family.

From his plan of reprinting the book as it stood, with no more annotation than was absolutely necessary, the editor has departed only in one point. The appendix containing "additional examples of the form of capture" has been re-cast and enlarged upon the basis of a paper of J. F. McLennan published in the *Argosy* in 1866, but with additions from other and more accurate sources. The reasons for adopting this course are obvious: the new matter in this appendix could not conveniently have been reserved for the promised second volume, and the facts are so arranged and explained as to confirm the author's argument, and effectually dispose of the notion that the form of capture in marriage is to be explained by maidenly bashfulness.

It will be seen from this brief account that, sparing as the editor's additions are, they make the new edition of the "Studies" well worthy of the attention of those who already possess the book in its older form. And to the not small class of students of early society who know McLennan's work only at second hand or by one hasty perusal, it may not be unprofitable to say that this is emphatically a book of which a general knowledge is not sufficient, inasmuch as some of the most important and interesting points are precisely those which are almost sure to be missed on a first reading. For this, perhaps, McLennan himself is partly responsible, for in giving to "Primitive Marriage" the subordinate title "an inquiry into the origin of the form of capture in marriage ceremonies," he seems to fix attention on what is only the starting-point of a far-reaching research. In print and in conversation one often meets with the notion that the doctrines of marriage by capture and kinship through women only are mere archæological *curiosa*, and that for the study of later law and custom it is quite indifferent whether these things are true, or whether, on the contrary, mankind started from the first with male kinship. But the importance of McLennan's researches lies largely in the demonstration that the structure of society under a system of kinship in the male line which has been preceded by kinship through women cannot be the same as would be reached by a race which has had male kinship from the first. Other writers have taught a doctrine of the priority of kinship through women, but no one except McLennan has accurately developed the consequences of the doctrine, and shown how it solves a problem which, though ignored by most writers, is of the highest importance, namely, the origin of *gentes* within a nation. Like all really original thinkers, McLennan has for one of his chief merits that he recognised the existence of difficult problems in matters which ordinary people pass over without seeing any difficulty at all. And therefore precisely those passages in his writings which on a hasty reading seem needlessly laboured and proper to be skipped are found upon re-perusal to be particularly useful and stimulating.

A word may be said in conclusion on what is promised for the second volume. It is satisfactory to know (p. 75) that it will include a short essay on the origin of exogamy. And from a note at p. 176 it may be inferred that in this essay the origin of exogamy will be sought in a state of society where marriage by capture was an established custom. We are also promised (p. 63) an essay on the marriage law of the Australian Kamiraloi, one of those highly complex problems in which McLennan's powers of analysis ought to appear at their best. From notes on pp. 109 and 228 it appears that part at least of McLennan's hitherto uncollected essays in the *Fortnightly Review*, including the papers on Totemism, or "On the Worship of Plants and Animals" (1869-70), will also be republished. It is to be hoped that in these reprints the editor will allow himself, in one direction, greater freedom of annotation than in the present volume. The Totem papers are in some respects the least finished of McLennan's writings, the evidence of totemism in the nations of ancient civilisation being much too largely drawn from second-hand sources. This gives an appearance of weakness to the whole structure of the argument, which has been very prejudicial to the influence of a most original and striking investigation. In point of fact a few of the detailed pieces of evidence ought to be abandoned altogether, but enough remains to leave the substance of the argument unaffected, and this ought to be clearly brought out by notes, referring to original authorities of unquestioned reputation, or giving up statements that cannot be authenticated. Even in the present volume one misses some notes of this kind. The polyandria of the Athenians (p. 235) rests on better evidence than the story which Augustine cites from Varro (Clearchus *ap.* Athen. xiii. p. 556 d.). Again, the note at p. 47, in which an attempt is made to prove the existence of the form of capture among the Hebrews from the phrase "to take a wife," ought rather to have been withdrawn than again built upon by the editor at p. 181; and what is said of the marriages of the Persians at p. 219 *sq.* requires careful revision.

W. ROBERTSON SMITH

BRITISH HYMENOMYCETES

British Fungi, Hymenomycetes. By Rev. John Stevenson. With Illustrations. Vol. II. Cortinarius—Dacrymyces. Pp. 336. 8vo. (Edinburgh: William Blackwood and Sons, 1886.)

WE are glad to welcome this second volume so speedily after the first, although we fear that expedition has been secured by some sacrifice of efficiency. It is a misfortune when the reader is impressed at once with the feeling that a volume has been hurried out to meet certain exigencies. That feeling is by no means absent in scanning these pages. As soon as p. 165 is reached, and there is no longer Fries's "Monographia" to fall back upon, *descriptions* give place to *diagnoses*, notwithstanding the remarks in the preface, which would seem to regard diagnoses with something of contempt. From p. 166 to the end the *student* must be content with the diagnoses from Fries's "Hymenomycetes Europæi," although there might have been collected together valuable notes from Fries's "Systema," Observationes," and "Elenchus." Nevertheless some advantage has been taken of the few descriptions published in the letterpress to Fries's "Icones."

It is of considerable importance to students that a work which professes to include all British species, up to date, should satisfy all reasonable expectations. The first volume omitted some forty species, and the present is by no means perfect. We open at p. 232, and find under the genus *Solenia* one solitary British species recorded, that of *Solenia ochracea*. Surely our author could not have been ignorant of the fact that *Solenia anomala*, P., is still more common, and was recorded by Berkeley in the "English Flora" (p. 199) fully fifty years ago. Neither could he have forgotten that another species was included in Cooke's "Hand-book" (p. 329) under the name of *S. candida,* since corrected to *S. fasciculata*. As these specimens were collected near Batheaston, by no other than Mr. C. E. Broome, and confirmed by the Rev. M. J. Berkeley, no doubt can be entertained of their being authentic. Furthermore, the name was corrected and the species figured by Berkeley and Broome in the *Annals of Natural History*, December 1870, No. 1301. The fourth species is *Solenia stipitata*, Fuckel, of which there are specimens in the Kew Herbarium. It cannot be conceded that a "Flora" satisfies all reasonable expectations when in one genus only one of four species is recorded.

Turning to an allied genus, that of *Cyphella*, we seek in vain for *C. Curreyi* or *C. albo-violascens* (which may be identical), *C. cyclas*, Cke. and Phil., *C. punctiformis*, Fries, *C. villosa*, Pers., all but one of which are well-known and widely-distributed species.

Whether the species under the genera *Stereum* and *Corticium* might have been arranged in a manner more in accordance with modern ideas, and far more useful to the student in their identification, may be left an open question. Those who are not facile in the use of the microscope may find it convenient to follow Fries, who paid little attention to microscopical characters, but surely in a large and difficult genus, such as *Corticium*, no assistance should be despised.

We observe, with some surprise, the genus *Microcera*, of Desmazières, included in a work devoted to British Hymenomycetes (p. 308) with the intimation "no British species." The fact is that *Microcera coccophila*, Desm., which is the type of the genus, has been found in Britain, and is recorded on p. 556 of Cooke's "Hand-book," and furthermore it is also true that it is not a Hymenomycete at all, but the conidia of one of the *Sphæriacei*, and is included as such in Saccardo's "Sylloge Fungorum" (vol. ii. p. 513). This singular double error might have been avoided had some mycologist been consulted who had not confined his attention exclusively to the Hymenomycetes.

The limits of species is another open question, and it is scarcely advisable to make too much of the insertion of what some may regard as doubtful species in a "Flora" wherein the author is not free to give reasons in their favour; nevertheless, we venture to hint that *Polyporus armeniacus*, Berk. (p. 215), is generally admitted to be only a resupinate condition of *P. amorphus*, Fries, and should not be continued as a distinct species. *P. Herbergii*, Rost (p. 195), is placed as an ally of *P. sulphureus* in the section "Caseosi," whereas *P. cuticularis* is found (at p. 202) in "Spongiosi." Unfortunately for this arrangement, the two species (*P. Herbergii* and *P. cuticularis*) are so closely allied that sometimes it is difficult to distinguish the one from the other, except by the difference in size of the pores, and hence some regard them as varieties of one species. At any rate, there is no good reason why such closely-allied forms should be separated by four-and-twenty intermediate species.

The mention of localities for species throughout the work is so vague, that some explanation should have been offered. When only one locality is given, the inference which would be drawn by the majority of readers would be that no other British locality was known at the time for that particular species. That this conclusion would be wrong is manifest from *Hydnum Weinmanni* (p. 242), which may be taken as an example. The locality cited is "Bristol," but Bristol is not the only, or the most important station for this species in Britain, because it occurs plentifully in the neighbourhood of Carlisle. If the intention was simply to indicate the locality where the species was first found in these islands, then again we fancy it is inaccurate, because, as we believe, it was first discovered by the late Rev. A. Bloxam, at Gopsall. The only solution we could suggest is that "Bristol" is the locality mentioned in Berkeley's "Outlines," and it was accepted as the only authentic record, without inquiry. Some species are stated to be "common," others "frequent," and others "rare," and when, in the absence of any one of these terms, a single locality is given, it is a fair inference that only one locality was known to our author, and that was the reason why it was given. Assuming this to be the case, we fancy that a very large number of these single localities could be challenged as not unique.

In addition to a "Glossary" of five pages, we are glad to find a good index of genera and species, but we search in vain for any clue to the contractions, in some cases only a single letter, employed in quoting authorities. Under nearly every species follows a line or two, sometimes five or six lines, of hieroglyphics, to which figures are appended. It may be all clear enough to the Rev. John Stevenson what is intended to be conveyed by "Quel. t. 11, f. 1," or "Viv. t. 27," or "C. Illust., pl. 276," but who these illustrious persons are, or what they have done, to be curtailed in such wise, is nowhere indicated. Surely the author must have determined upon giving a key to these mysteries when he first commenced to employ them, and, in the hurry to issue the second volume, quite forgot the "students," even if he remembered the "scholars," and closed the book before he had finished his work.

A summary of the contents of these volumes, as they stand, exhibits the following results as compared with the last preceding work on the same subject:—

"Hand-book of British Fungi" ...	1044
Stevenson's "British Fungi"	1675

or, an addition of 631 species of Hymenomycetes since the year 1871. The majority of the additions have been made in the Agaricini, which stand thus:—

"Hand-book of British Fungi" ...	699
Stevenson's "British Fungi"	1183

or, an addition of 484 species, leaving only 147 species to be distributed over the residue of the genera of Hymenomycetes. These results are at any rate a justification, if any were needed, for the publication of a new work, especially when the older one is entirely out of print.

There can be no doubt that all that portion of the work which contains translations from the "Monographia" of Fries will be exceedingly valuable to British mycologists, and this extends through the whole of the first volume and 165 pages into the second; the only regret being that the few remaining species, which have not as yet been recorded in these Isles, were not inserted in brackets, or published as an appendix, so that the whole of Fries's excellent work might have been in the hands of every mycologist in this country. Perhaps even now such an appendix might be published, and no doubt it would meet with a hearty welcome.

Despite of such strictures as we have been impelled to make, we venture to hope that the present edition will soon be exhausted, and that its author will be called upon to prepare a new and revised edition, with a key to all the mysteries of the old one. M. C. C.

THE OCEAN

Der Ozean. Von Otto Krümmel. (Leipzig und Prag: Freytag-Lempsky, 1886.)

THE great interest which oceanographical studies have aroused within the last few years is shown in a marked manner by the publications destined to popularise the notions acquired respecting this vast and important chapter of physical geography. Not long after the appearance of the "Lehrbuch der Ozeanographie" by Boguslawski, whose untimely death has interrupted the publication of the second volume, we have a new and small manual by Dr. Otto Krümmel, whose name is already known to oceanographers.

This little treatise is clearly written, and the most important general notions concerning the physical geography of the sea are well stated, and discussed with ability. The author has succeeded in expressing briefly the essential notions about the ocean, which have been recently acquired by the *Challenger* and other deep-sea expeditions.

The author describes, in the first place, the ocean's surface and its subdivisions ("Die Meeresflächen und ihre Gliederung"); discusses the relation of oceanic and terrestrial areas from the point of view of their respective size; indicates the distribution according to hemispheres; and points out the classification he has adopted into *oceans*, properly so called, with their general systems of ocean currents, and *secondary seas*, which are more or less cut off from the great oceans. The *secondary seas* are again subdivided into *interior*, or *inter-continental*, and *border seas*, situated on the outer edges of the continents. The volume of oceanic water is then estimated. In the second chapter the interesting questions connected with the deformation of the level and surface of the ocean, owing to the attraction of the continental masses, are examined The depths and contours of the ocean basins are next pointed out, and the work of the *Challenger* and other deep-sea expeditions, together with the apparatus employed, is described. The observations of the *Challenger* upon the nature and distribution of deep-sea deposits are summarised. The physical and chemical properties of sea-water are set forth in a special chapter—the salinity of the ocean, its distribution and origin; the gas contents; the transparency and colour, are, in turn, treated of. After having made known the principal phenomena regarding the temperature of the ocean and its distribution, Krümmel treats of the glacial phenomena of the Arctic and Antarctic Oceans, pointing out the limits of the floating ice and icebergs in each region, and the influence of these regions on the questions of general oceanic circulation. The last chapter is reserved for a consideration of the movements of water, such as currents, waves, and tides.

Such is the general order and method of this manual. There is no attempt to give any general notion of the life of the shores, deep sea, and surface of the ocean, or of any of the phenomena due to organisms. The author shows himself to be everywhere *au courant* with the most recent discoveries in his subject. It would appear, however, that he has not had an opportunity of consulting the "Narrative of the Cruise of the *Challenger*," published last year, or he would have embraced in his descriptions some additional interesting details and general views. The work is illustrated by many woodcuts and small charts, some of which are instructive, others conveying little information to the reader, but when the low price of the book (one shilling) is remembered it would be unfair to criticise closely these illustrations. Dr. Krümmel has attained the object he had in view—to popularise in a scientific manner our knowledge relative to the physical geography of the sea, a subject full of interesting questions for all cultured minds. J. M.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

On the Connection between Chemical Constitution and Physiological Action

As regards Dr. Brunton's letter in last week's NATURE (p. 617), I would express myself as more than satisfied with the personal explanation, but Dr. Brunton has not noticed the most important point to which I wished to call attention, viz. that whatever may be the value of my experiments, as showing a connection between physiological action and chemical constitution, the researches of Crum Brown and Fraser have really no bearing on the subject, for the simple reason that they had no knowledge of the chemical constitution of the re-agents they employed. There is an old receipt for cooking a hare which commences "*First catch your hare*," and in attempting to show the influence of change in chemical constitution on physiological action, it is well first to get a constitution. In the last edition of Watts's "Organic Chemistry" (1886) it is stated, "All these bases (the alkaloids), like the amines, are derivatives of ammonia, but their molecular structure is for the most part unknown." Even as regards inorganic compounds, our knowledge of their chemical constitution is not the most definite, but I believe that the arrangement of the elements in isomorphous groups expresses most clearly the resemblance in the chemical constitution of their compounds.

After again reading carefully Dr. Brunton's paper, I must confess that I cannot find anything showing the connection between chemical constitution and physiological action, except, perhaps, in the case of the alcohols. Here we have a class of bodies in which the different members of the series have probably the same relation to each other as the elements in the same isomorphous group, and it is an interesting fact that not only do they resemble each other in their physiological action, but that their toxic action increases with their molecular weight, as I have shown to be the case with the inorganic elements, where, in each isomorphous group, the toxic action increases with the atomic weight of the elements.

In conclusion, I would reprint an extract from a paper published forty years ago :—"A moment's reflection on the problems to be solved will suffice to show that experiments conducted with this class (inorganic) of substances are more likely to furnish useful results than those made with bodies derived from the animal or vegetable kingdom, although, owing to the striking effects caused by some of these substances, physiologists have mostly directed their attention to them. By so doing, however, we are employing re-agents with the properties and composition of which we are imperfectly acquainted, to the neglect of those on the nature of which chemistry has already thrown much light, for not only are we better acquainted with the more purely chemical properties of inorganic compounds, but their relation to heat, electricity, and molecular polarity has been to a considerable extent made out." JAMES BLAKE

Disinfection by Heat

IN Dr. Parsons's Report on Disinfection by Heat (NATURE, vol. xxxiv. p. 583) occurs the statement: "It appears that there are no tables or formulæ in existence by which the degree of humidity of the air corresponding to a given difference between the wet and dry bulb thermometers at these high temperatures can be ascertained." There are both tables and formulæ; but the tables are the numerical values for the formulæ, and such tables are to be found in Balfour Stewart on "Heat," Dixon's "Treatise on Heat," Blanford's "Meteorologist's Vade-mecum," and numerous works on the steam-engine.

Let the degree of humidity be represented by h; vapour-tension at dew-point by x; wet-bulb temperature by t, its vapour-tension by f; dry-bulb temperature by T, its vapour-tension by F; barometric pressure by b. Then, the theory of the dew-point gives

$$h = \frac{x}{F};$$

and

$$x = f - \frac{0 \cdot 382\,(T - t)b}{1115 - 0 \cdot 7t};$$

hence

$$h = \frac{f}{F} - \frac{0 \cdot 382\,(T - t)b}{(1115 - 0 \cdot 7t)F}.$$

The tables give the vapour-tension, consequently if T, t, and b are known, h can be found. At these high temperatures the degree of humidity would probably not be required very accurately. If within 1 or 2 per cent. of accuracy would suffice, the second term may be omitted. This results from the fact that the higher the temperature of the air, the nearer is the dew-point to the wet-bulb temperature.

The quantity sought then is $h = \frac{f}{F}$. Given $T = 299$, 299, and 249; $t = 146$, 165, 190; and taking F and f in pounds from a table in "Lardner on the Steam-Engine":—

(1) $$h = \frac{3 \cdot 5}{63} = \cdot 05;$$

(2) $$h = \frac{5 \cdot 5}{63} = \cdot 08;$$

(3) $$h = \frac{9 \cdot 5}{29} = \cdot 32.$$

Here saturation is represented by unity. This is at once a short and simple method of calculating the degree of humidity at these very high temperatures. If the barometrical pressure were observed, and the long second term worked out, the results would not be materially different, but would be something less.

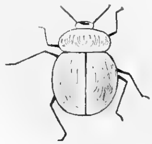
The Beetle in Motion

MUCH has been written on "the horse in motion." Can any readers of NATURE supply me with references to published matter on the subject of hexapod progression?

The few observations I have made may be summed up in a few words. I use the letters r and l to signify the right and left legs respectively, and number the limbs from before backwards. When walking rapidly the appearance is as if l 1, r 2, and l 3 moved forward together simultaneously, alternating with r 1, l 2, and r 3. When the pace is slower it is seen that l 1 and r 2 start together and come down at about the same time, some-



times one sometimes the other being a little the first. Then, lifted almost but apparently not quite at the same time, l 3 starts. The motion of this leg being somewhat slower, and the limb having further to travel, the foot generally comes to the ground appreciably later than l 1 or r 2. The general effect is to produce, at the moments of pause between the strides, the position indicated in the figure, which differs considerably from the conventional position delineated by artists who seek to represent the beetle in motion. C. LLOYD MORGAN

University College, Bristol

The Astronomical Theory of the Great Ice Age

IN Sir Robert Ball's paper on this subject, which appears in your last number (p. 607), that author states that the calculation given "has convinced him that Mr. Croll's theory affords an adequate explanation of the Ice age." It is more in the hope of obtaining from Sir Robert a statement of the grounds of this conviction than for the purpose of controversy that I write this letter.

It will of course be conceded that the frost and snow of a single winter, melted off during the following summer, would not produce an Ice age. But, on Sir Robert Ball's figures, the increase of winter cold at the period in question was accompanied by a corresponding and equal increase of summer heat. Why, then, should the latter prove insufficient to melt the winter accumulation of snow and ice in any locality where it now suffices to melt it?

The question is one of the joint result of two opposing forces. Both, under the supposed conditions, are intensified and equally intensified. How does this affect the result? More snow and ice is doubtless formed in the winter, but then more heat is employed in melting it during the ensuing summer. Why, then, was it not melted in any place where it is now melted? A kind of answer to this question may be extracted from the writings of Mr. Croll, but not, I think, a satisfactory one. I am therefore anxious (in common, I am sure, with many others of your readers) to hear the reply of Sir Robert Ball.

Llandudno, October 25 W. H. S. MONCK

The Enormous Loss from Ox-Warble

I VENTURE to solicit your co-operation in making some points better known in order that farmers may be better able to protect themselves from the enormous loss from warbles on cattle from the bot-fly, positive proof having been furnished that it largely exceeds 2,000,000*l*. to 3,000,000*l*. yearly! To begin: I appeal to those farmers who have somewhat studied the question to make it clear to those who have not done so that *each warble lump has a large maggot under it*, feeding on the juices of the hide or flesh. These lumps many call "health lumps" or "thriving bumps," and *seem to prefer that their cattle should have them*. It is readily seen how this serious fallacy has arisen, viz. from the fact that the warble lumps begin to show about Christmas (from the growth of the maggot under them), which also happens to be the time that the cattle receive their most nourishing food, and are then warmly housed or sheltered. But there could be no greater mistake than to think that the swellings from the ravages of these horrid maggots are proof of a thriving condition! A correspondent writes me: "Since reading recent issues on the ox-bot or warble-fly, I have visited several cattle markets and slaughter-houses to see for myself if the ravages of the maggots are so serious as the statements led one to believe. I must frankly state that what I have seen convinces me that the statements are much under the mark rather than over it. The first beast I handled showed 42 warbles, some only 3 to 6, whilst many others showed 30 to 70; and on examining hides at slaughter-houses this state of things was again confirmed (the warbles are more readily seen upon the *under*-side of the skin, and many are small ones that would not show as a lump. I am certain a farmer has only once to make such a visit to be not only convinced of the great loss, but also, if he has any neighbourly feeling about him, to make him call the attention of his brother-farmers to the subject."

I am anxious to indorse this recommendation, for the farmers should now satisfy themselves as to the actual state of the matter, as in a few weeks from now the warble lumps will have vanished, and I fear the farmers will hardly take protective measures during the summer, when the warbles are not visible, unless they are convinced; whilst seeing would be believing. I may remark that the following simple remedies are all efficacious to destroy the maggots: mercurial ointment and carbolised oil, to be applied with caution by a careful man; or, better still, quoting from the Report of the Royal Agricultural Society, "As a general application, safe in all hands, McDougall's preparation has proved excellently useful," and I have convinced myself it is the best and safest remedy that can be applied, not only for destroying the maggots, but, later on, as a wash to prevent the attacks of the flies. I would not have occupied so much of your space, but I am convinced this is a subject of national importance. JOHN WALKER

Southport

P.S.—Farmers wishing for further information should read "Observations on Ox-Warble or Bot-Fly," 1884, and a second Report on "Ox-Warble or Bot-Fly," 1885, by Eleanor A. Ormerod, F.R.Met.Soc., &c. (London: Simpkin, Marshall, and Co.), and a new pamphlet called "The Bot-Fly," just issued by J. C. Jack, Grange Publishing Works, Edinburgh. This work fully defines every minute detail of the history, life, prevention, and losses sustained by the dreaded pest.

Aurora

THE remarkable aurora borealis observed by Prof. Piazzi Smyth at Edinburgh on July 27 (NATURE, vol. xxxiv. p. 312) seems to have been visible over a very great area. In my meteorological journal it is remarked on July 27 that the bright silver-clouds appeared beautiful between 9.30 and 11 p.m. "The colour of the northern sky above the silver-clouds was misty and brownish, though not cloudy." I had never seen such a tint in the sky. I have no hesitation in saying that the unusual darkness was the same as observed at Edinburgh. The fair white arc I did not see; clouds came up at midnight. It may be interesting to state that I also saw, on July 26 at 9.30 p.m., an aurora-like white cloud in the north-west. This cloud was very different from the well-known silver-clouds so often described in 1885 and 1886. On the 28th and 29th nothing extraordinary is mentioned in my journal, but on the 30th faint traces of the silver-clouds and again "a very strange yellow-brownish colour of the north and north-west sky" are remarked. The great aurora on March 30 we also observed very well at Königsberg. F. HAHN,

Professor of Geography at the Königsberg University

Königsberg, Prussia, October 25

Earthquakes

IT is always interesting to look for coincidences in the earthquakes in different parts of the world. In NATURE, vol. xxxiv. p. 627, you announce that a violent earthquake was felt at Charleston and many other places in the United States of North America, on the 22nd inst. at 3 o'clock in the afternoon, *i.e.* 20h. 20m. Greenwich time. On the same day a very slight shock is recorded as having occurred at Neuchâtel, Switzerland, at 9h. 20m. evening, Berne time, *i.e.* 20h. 50m. Greenwich time. It is not impossible, but I must confess scarcely probable, that the faint shock at Neuchâtel was the re-percussion of the severe earthquake of North America. F. A. FOREL

Morges, Switzerland, October 31

IN connection with Prof. O'Reilly's letters in NATURE of October 14 and 28 (pp. 570, 618), and your notice of October 21 (p. 599), I supply a few data, which at first I thought of too little interest for your columns. At 6.12 p.m. local time (17h. 41m. universal time), on October 16, two shocks occurred with a short interval, the direction being approximately that of the meridian. The intensity was such as might be produced by very heavy carts passing. H. DU BOIS

Strasburg, October 31

Meteor

THIS evening, at about 8.25, I saw a magnificent meteor, of a blue colour, falling a little to the left of the Pleiades.

Belfast, October 31 JOSEPH JOHN MURPHY

FREDERICK GUTHRIE

FREDERICK GUTHRIE was born in Bayswater on October 15, 1833, and was the youngest of six children. His father, Alexander Guthrie, was a tailor, carrying on business in New Bond Street, and is said to have been a man of literary taste and ability; that he was a man of cultivation is shown by the education he provided for his children, one of whom, Francis, early distinguished himself at University College, London, and at the London University, as a mathematician, and is now Principal of the South African College, Cape Town. As a boy, Frederick Guthrie was taught privately until his twelfth year by the late Henry Watts, F.R.S.; afterwards he was sent to University College School, then under the head-mastership of Prof. Key, whence he passed into University College, London. There he remained three years, the last two of which were devoted mainly to the study of chemistry, under Profs. Graham and Williamson, and of mathematics under De Morgan, a teacher with whom it was impossible for a young man of Guthrie's power to come into contact without receiving a life-long impress. There also he again came into contact with Watts, who was then principal assistant in Prof. Williamson's laboratory, and an intimate friendship was cemented with his old tutor that remained unbroken till the death of the latter. In the spring of 1854 Guthrie went to Germany to continue his chemical studies, and worked first at Heidelberg, under Bunsen, and then at Marburg, under Kolbe, where he took the degree of Doctor of Philosophy ("*summa cum laude*") in 1855, having previously graduated as Bachelor of Arts of the University of London. After returning to England he was appointed, in 1856, assistant to Dr. Frankland, then Professor of Chemistry in Owens College, Manchester. In 1859 he went to Edinburgh as assistant to the late Vice-President of the Council, who had just succeeded Dr. William Gregory as Professor of Chemistry in the Edinburgh University.

Two years later Guthrie accepted the Professorship of Chemistry and Physics in the Royal College, Mauritius. He arrived in the island in May 1861, and for six years he devoted himself to endeavouring to introduce and establish on a durable basis scientific instruction in the colony. Here one of his colleagues was Mr. Walter Besant, the eminent novelist, with whom he formed a friendship that remained intimate and uninterrupted through life. He returned to London on leave in 1867, and in 1869 he was elected Lecturer on Physics in the Royal School of Mines, a post which, with extended duties and modified title, he retained till his death.

In the spring and early summer of this year many of Guthrie's friends remarked upon his looking ill and seeming to be in low spirits. After a while he complained of a difficulty in swallowing, which presently became so serious that he was unable to take solid food. When at last he was prevailed upon to consult a physician, it was discovered that he was suffering from cancer of the throat. He sank rapidly during the last two or three months, and the inevitable end of his disease came on October 21. He was buried in Kensal Green Cemetery on the 26th.

Such were some of the chief outward and visible stages in Frederick Guthrie's career. Perhaps the first thing to strike any one on making his acquaintance was his strongly-marked individuality. His opinions were, much more than most men's, of his own forming, not simply picked up as they floated about in talk or in print. And his conduct followed his opinions: he did what he thought right, with very little regard to the consequences to himself, or to what might be thought of him by others. His scientific knowledge, too, was, much more than most men's, of his own getting, the result of his own observation and experiment. In others, also, he valued even a small scrap of self-gotten knowledge more than a large store of secondhand erudition. In this respect he sometimes went to excess, and, though not without mathematical knowledge, he was somewhat apt to underrate the scientific importance of the work of mathematical physicists in comparison with that of pure experimentalists. But even this mistake had root in the thoroughly sound conviction that it is the duty of a man of science to be a strictly faithful interpreter of the observed facts of Nature, and that, the further he ventures in the field of theoretical deduction the more room is there for self-deception. He seemed, however, sometimes to forget that phenomena do not present themselves to the natural philosopher ready clothed in words, and that all that can be expressed in human language is the conception formed in the mind of the observer. The true function of the mathematical physicist is in reality, as Kirchhoff has pointed out, nothing more than to find out the simplest statements that are consistent with observation.

Guthrie's devotion to science was complete and single-minded. He had a deep conviction of the value and dignity of any kind of genuine, self-forgetful, scientific work, and he knew how, if necessity arose, to claim the dignity due to a sharer in such work. But from affectation or vanity he seemed entirely free. His wonderful gift of humour and power of terse and telling speech made it easier for him, than for most men, to put down any approach to impertinence or presumption; but, except where he felt that a lesson was needed, he was most considerate of others, both in speech and action. He delighted in playful mystifications (see, for example, Prof. von Nudeln's letter in NATURE, vol. xxi. p. 185, on the "Potential Dimensions of Differentiated Energy"), but his drollery was never ill-natured. He was generous and kind-hearted in the extreme; as a friend he was steady and faithful. Although essentially a man of science, he had considerable literary attainments, and had an excellent knowledge of both German and French, while his powers of literary expression were remarkable. It will not astonish those who knew his ability in this direction to learn that as a young man he published (under the *nom-de-plume* of Frederick Cerny) a poem called "The Jew," and a metrical drama called "Logroño."

With regard to Guthrie's scientific position and achievements it may be remarked, in the first place, that he belonged to a class that was probably commoner in his generation, and in that which preceded it, than it is likely to be in the future—that, namely, of physicists who served their time as chemists. Until within the last twenty years or so the only accessible school of experimental science was a chemical laboratory, and consequently, for the last two generations, a large proportion of the most prominent physicists have been men who began their scientific career as chemists. Among many others, it may suffice to mention Faraday and Regnault. Guthrie's first published investigation seems to have been his dissertation on taking his Ph.D. degree; it was entitled "Ueber die chemische Constitution der ätherschwefelsauren Salze und über Amyloxydphosphorsaure." In the six years between taking his degree and going to Mauritius, he published eight or ten papers, mostly on points of organic chemistry—one of them, on the amyl group, contains the discovery of the therapeutic action of nitrite of amyl, and suggestions for its introduction into the pharmacopœia. His first physical investigations were published while he was in Mauritius, and included two researches into the formation of drops and one into the properties of bubbles. It is striking evidence of the reality of Guthrie's love of science and of his force of character that, under circumstances in almost all respects adverse to scientific work beyond what was required by his official position, he should have persevered steadily with his experiments and produced papers of great value. While in Mauritius he also published a paper on the iodide of iodammonium, and a pamphlet on "The Sugar-Cane and Cane-Sugar," and made complete analyses of the waters of the principal rivers of the island. After his return to England his scientific work was almost wholly confined to physics, but it is perhaps significant of the side from which he approached the study that the subjects that occupied him principally had relation to what is usually called in the text-books "molecular physics." Among many other researches the following may be specially mentioned: on the thermal conductivity of liquids; on approach caused by vibration; on stationary vibrations of liquids in rectangular and circular troughs; on salt-solutions and attached water (the results of this investigation were contained in a series of eight papers, and included the discovery of the substances named by Guthrie "cryohydrates," a class of solid hydrated salts which melt without change of composition, in most cases below 0° C.); on "Eutexia," an investigation into the properties, especially the melting-points, of metallic alloys and mixtures of salts.

As a teacher, it has been well said of Guthrie by one who knew him well, that "he did not desire merely to fill his pupils' heads, but to make them use them"—a far more valuable but more difficult result to attain. A large proportion of his pupils consisted of "certificated science teachers," and for these he introduced a system of instruction, consisting largely in making them construct with their own hands the apparatus required for their experiments, which was probably more fruitful (especially in the case of this particular class of pupils) than any other that he could have adopted.

In 1873 Guthrie issued to his scientific friends a characteristically worded little circular, which resulted in the formation, early in the following year, of the Physical Society of London, a Society which now includes, with very few exceptions, all the leading physicists of the United Kingdom. Through his intervention, permission was obtained from the Lords of the Committee of Council on Education for the meetings of the Society to be held in the Physical Laboratory of the Science Schools at South Kensington. He chose for himself the somewhat onerous post of "Demonstrator" to the Society, and in this capacity placed his time and the resources of his laboratory freely at the disposal of those who wished to exhibit experiments or apparatus at the Society's meetings. It was not till 1884 that he consented to become President.

In the early part of the present year he gave a course of three lectures before the Society of Arts on "Science Teaching," in which he advocated with equal vigour and humour the advantages of a training in experimental science.

Besides the poetical works already mentioned, and his numerous papers on scientific subjects, Guthrie was the author of the following books:—"Elements of Heat and Non-Metallic Chemistry," "Electricity and Magnetism," "Molecular Physics and Sound," and "The First Book of Knowledge."

He was elected a Fellow of the Royal Society of Edinburgh in 1859, and a Fellow of the Royal Society of London in 1873. G. C. F.

THE LONGEVITY OF GREAT MEN[1]

THE conclusion that the intellectual giants of the race are favoured by an abundance of years on the scene of their heroic activity, and are thus further differentiated from their more common fellow-men, seems natural, and has been accepted upon evidence which, in a less pleasing conclusion, would be considered ridiculously insufficient, and even false. The usual method of attempting to answer the question whether great men are longer-lived than others, is to prepare a list of the ages, at death, of a number of eminent men, take the average age, and compare it with a similar average of a number of ordinary men, or even with the average lifetime of the race, and in this way to make the results speak decidedly in favour of the superior longevity of great men. All that such a method can prove (and this it does prove) is that it takes long to become great. It neglects to consider that a select class of men is dealt with, and that, to be even potentially included in this class, one must have lived a certain number of years.

For example: in an article translated in the *Popular Science Monthly* for May 1884, it is argued that astronomers are a long-lived race because the average life-period of 1741 astronomers is 64 years and 3 months. An average human life is only 33 years; but as one cannot be an astronomer before adult life, the author takes the expectation of life at 18 years, which is 61 years, and thus makes an excess of over 3 years in favour of astronomers. He also divides his astronomers into four degrees of eminence, and finds that those of the first rank live longer than those of the second, and they in turn longer than those of the third, and so on, thus implying that the best astronomers are most favoured with years. The true conclusion is, that it takes longer to become a first-rank astronomer than it does to become a less eminent one.[2]

If great men were great from their infancy, and we had the means of ascertaining this fact, the method would be correct. But, as it is, we must define in some way or other what we mean by greatness, and then fix the average age at which it becomes possible to distinguish an amount of talent sufficient to enable its possessor to be enrolled in the ranks of the great as already defined. What is known as the "expectation of life" at any number of years tells the most probable age at death of one who has attained the years under consideration: a comparison of this age with the age at death of great men will decide whether they are longer-lived or not.

The attempt was made to select about 280 to 300 of the greatest men that ever lived.[3] Throwing out about 30 of the doubtful names, there remain 250 men, about whom the statement is hazarded that a list of the 250 greatest men, prepared by another set of persons, will not materially differ from our list, as far as all the purposes for which it is to be used are concerned. From this list I have selected at random a set of men of whom it was probably easy to fix the age at which they had done work which would entitle them to a place on this list, or work which almost inevitably led to such distinction: it is a date about midway between the first important work and the greatest work. The average of over 60 such ages is 37 years; which means, that, on the average, a man must be 37 years old in order to be a candidate for a place on this list. The real question, then, is, How does the longevity of this select class of 37-year-old men compare with that of more ordinary individuals? The answer is given by the expectation of life at 37 years, which is 29 years, making the average age at death 66 years. And this is precisely the age at death of these 60 great men; showing, that, as a class (for these 60 may be considered a fair sample), great men are not distinguished by their longevity from other men.

Further interesting conclusions can be drawn if we divide the men into classes, according to real psychological and physiological differences in the ways of manifestation of the several kinds of genius. It is almost surprising how well the ordinary trinity of faculties—intellect, emotions, and will—accomplishes this purpose. Greatness seems to appear either in a brilliant thought, a deep feeling, or a powerful will. Under men of thought would be included philosophers, scientists, historians, &c.; under men of feeling, poets, musicians, religionists, &c.; under men of action, rulers, commanders, statesmen, &c. Before comparing the relative longevity of these three classes of men, I assure myself that the period at which greatness begins to be possible does not materially differ[1] in the three classes, and, as was done in the former case, I exclude all cases of unnatural death. I find that men of thought live 69·5 years, or 3·5 years longer than ordinary men; while the lives of men of feeling are 3 years, those of men of action 5 years, shorter than those of average men,—a conclusion that agrees with the commonly accepted view on the subject. If we subdivide these three classes, we find, that, while all classes of men of thought live longer than ordinary men, the moralists live longest, scientists coming next; that among the men of feeling the religionists alone live the full period of life, while poets' lives are 5 years, and musicians' lives 8 years, too short; that, of men of action, rulers and commanders both fail to complete the full term of life by 4 years. One sees from these statements (which, however, in their detail at least, must be accepted with hesitation, owing to the fewness of examples) that the kind of psychical and physical activity pursued influences the life-period; that certain types of genius are apt to die young, while others are particularly favoured with a full allowance of years.

The question of longevity becomes important when we consider that through it the leaders of civilisation are allowed to exercise their important function a few years longer, thus enabling more great men to be alive at the same time; and that, by its tendency to be inherited by the offspring, the children of great men will begin life with a better chance of reaching maturity, and, in turn, of becoming important to the world, if, as we have reason to believe it would, the genius of their ancestors has left its traces in them. JOSEPH JASTROW

[1] From *Science*.

[2] Mr. Galton ("Hereditary Genius," p. 34) has allowed himself to neglect a similar consideration. In giving the number of men in each class that the population of the United Kingdom would have between certain ages, he gives 35 as the number of men of class *G* (a very high degree of eminence) between the ages 20 and 30, and only 21 such men between 40 and 50 years. But this cannot be true, because only a very small proportion of men could possibly attain the eminence requisite to be classed among the *G*'s in 20 to 30 years, while almost all (of those who will attain it at all) will have attained it before the end of their fiftieth year. And this consideration far outbalances the excess in absolute number of men between the former ages over those between the latter. Similarly the falling-off in the number of men of class *g*, *i.e.* idiots, from decade to decade, would be more rapid than in ordinary men,—a fact which the tables fail to show.

[3] The names were selected by three others and myself, while engaged in a study of what might be called the natural history of great men. The process of selection was most rigid and careful, by a system which it would take too long to describe.

[1] Mr. Sully (*Nineteenth Century*, June 1886) has shown that men of feeling are more precocious than men of thought; but the difference in the age at which their first great work is done, though in favour of men of feeling, is very slight indeed.

THE GEOLOGY OF THE LEBANON

WE are indebted to Dr. Carl Diener, of the University of Vienna, for an able monograph on the geological and physical formation of the Lebanon and surrounding districts, accompanied by maps, sections, and illustrations reproduced from photographs.[1] Notwithstanding the observations of Russegger, Fraas, and others, on the physical features and structure of this region, a complete monograph on its geology has long been a desideratum, and the work of Dr. C. Diener forms a fitting continuation of the survey of Lartet in Palestine, and of the Palestine Exploration Society in Arabia Petræa and the Jordan Valley.

Down to a comparatively recent period, the ranges of the Lebanon and Anti-Lebanon were supposed to be formed of Jurassic limestones, but the observations of Oscar Fraas showed that this was an error, and that they are mainly formed of Cretaceous and Eocene limestones. It is only within the limits of a narrow belt at the western base of Mount Hermon that Jurassic beds really occur; this being their first appearance on proceeding northwards from Arabia Petræa. The formations overlying the Jurassic strata are referable to the "Neocomian" (?), Cenomanian, Turonian, Senonian, Eocene, and newer Tertiary periods; while great sheets of basaltic lava of late Tertiary age occur both to the north and to the south of the region embraced by the memoir.

Dr. Diener has worked out with great success the numerous lines of faulting and flexuring which the strata have undergone since their deposition, and which have been produced mainly during the Miocene epoch. Mount Hermon itself owes its position in a great degree to the elevation of its mass along the line of a great fault which coincides with its western base. Its beds of limestone, belonging to the age of the Lower Chalk of Europe, are disposed in the form of a low arch, the axis of which passes under the summit, and ranges in a north-north-east direction along the line of the heights of Anti-Lebanon. Other faults range along the southern and eastern flanks of the great dome-shaped mount which has thus been bodily upheaved in respect of the bordering strata. There can be no question that the system of terrestrial disturbances along which the Syrian mountains have been fractured and dislocated is the same as that which has given origin to the Jordan-Arabah depression; and amongst the lines of displacement traced out by Dr. Diener, we can have no difficulty in recognising that which is the actual prolongation of the leading fault of the Jordan Valley. This great line of fracture and displacement appears to enter the valley of the Leontes (Litany) at the western base of Hermon, where a complete change of the stratification takes place on either side, and the "Lebanon Limestone," with the subordinate Lower Cretaceous beds, are thrown into a nearly vertical position, and brought into contact with horizontal strata of the Upper Chalk (Senonkreide). It may therefore be inferred that the great valley of Cœle-Syria (El Bekâ'a), separating the range of the Lebanon from that of Anti-Lebanon, owes its origin, in the first instance, to the same system of faults which has caused the depression of the Jordan Valley, the original features having been modified by extensive denudation; and if we suppose that the primary line of fault reaches as far north as the Lake of Homs, in the valley of the Orontes, and as far south as the Gulf of Akabah, the distance through which this great line of fracture of the earth's crust will have been traced will amount to about 350 English miles.

Dr. Diener expresses some doubts regarding the former existence of glaciers in the Lebanon, notwithstanding the opinions of such observers as Hooker, Fraas, Girard, and others. Hooker especially identifies the mound upon which the grove of ancient cedars is planted as an ancient moraine. The author throws some doubt upon this view, because he was unable, after three hours of search, to find scratched or striated boulders, although he admits that, viewed in certain directions, the mounds do present the appearance of a terminal moraine. In reference to this subject, it may be observed that the position and altitude of the Lebanon Range makes it extremely probable that perennial snow, giving origin to glaciers, occupied the higher regions during the Glacial epoch. Amongst the Caucasus, which are only a few degrees further north, though somewhat higher, glaciers occur at the present day, and during the Glacial epoch the valleys were brimful of ice. Hence it would be strange if in the Lebanon it were proved that they had been entirely absent. The scarcity or absence of glacial striations, on which Dr. Diener founds his objection, is easily accounted for when we recollect that the blocks and stones consist of rather friable limestone which has been exposed through thousands of years to the effects of frost, heat, and rain. It is only when the surface of a rock, or of a boulder, has been protected by a coat of stiff glacial clay, that we can expect the striæ and scars to be preserved throughout a long period of time.

[1] "Libanon; Grundlinien der physischen Geographie und Geologie von Mittel-Syrien." (Wien, 1886.)

On another point Dr. Diener expresses his dissent from the views of previous observers, arising, as it seems to the writer, from his want of appreciation of the full effect of eroding agencies. The neck of land which connects the Râs Beyrût with the outer ridges of the Lebanon is formed of beds of stratified gravel or conglomerate rising from 120 to 150 feet above the sea. This is to all appearance an old sea-bed formed at a time when the land was submerged to the extent above indicated, during which Râs Beyrût was an island. The author cannot accept this view, because his observations of the coast-line of Syria, bearing on the present state of the harbours, do not appear to show a change of level of more than a few feet; less, in fact, than would be necessary to submerge the neck of land. On the other hand, he accepts the evidence offered by Lartet and the writer of a submergence of the coast of Southern Palestine and Philistia to an extent even greater than this, namely 200 feet and upwards; and he points to the evidence of great changes of level on the coast of Northern Syria and Asia Minor. May not the absence of raised beaches on the coast of Southern and Middle Syria be due to the waste caused by the wave action of the Mediterranean, which would tend to carry away such soft materials during the period of emergence where exposed and unprotected? In another case the author throws doubt on the observations of Dr. Post regarding the presence of shell-beds at levels of 150 to 250 feet near Lâdikîeh, an account of which appeared in NATURE, vol. xxx. p. 385, and which is given with much detail. It seems an instance of hypercriticism to call in question an authenticated statement merely on the ground that the author was unable to personally verify it.

The above instances will, however, go to show with what care and labour Dr. Diener has accomplished his task, and he is to be congratulated upon the production of a work which will doubtless be considered a standard of reference regarding the physical history of the Syrian mountains. I may perhaps be allowed to remark that his admirable geological map would have been improved by following the English custom of showing the dip of the strata by means of small arrows, and of distinguishing between ordinary boundaries of formations and those which are produced by faults and fractures, and the book itself would have been rendered easier for reference by an index.

EDWARD HULL

AUTUMNAL FLOWERING

THE "extraordinary gooseberry" season seems to have set in this year with more than usual severity. Country clergymen and amateur gardeners, who would see nothing unusual in the autumnal flowering of a hybrid perpetual rose (which reminds them, perhaps, of their old school-days, when they read of "*biferique* *rosaria Pæsti*"), are moved with astonishment at the sight of a second crop of flowers on an apple-tree or a laburnum. Common as the phenomenon is, however, not many persons, even among botanists, bestow a thought as to how it is brought about. Gardeners recognise two distinct modes in which flowers may be produced, either from the "old wood," meaning the wood formed in the previous season, or from the shoot of the present year's growth. A rhododendron with its flowers packed up in a "winter-bud" destined to unfold in spring, an apple or a laburnum with their winter-buds at the ends of short contracted shoots or "spurs," afford illustrations of the one type, while a rose, with its newly-formed shoots crowned with one or more rose-buds, supplies an example of the latter. There is the same sort of difference between these two kinds of flowers that there is between the so-called "annual" plants whose course of life is outrun in a single season, and "herbaceous perennials" which die down in winter, leaving a winter-bud to carry on the work when circumstances become propitious in spring. The second growth of flowers in autumn may, therefore, be due to two different causes. In the one case it is an anticipation of spring; the flowers being produced afore time. Conditions of growth being persistently favourable, the winter-bud, instead of remaining dormant, bursts prematurely into growth, and repeats in autumn what its predecessor had done in spring. The great difficulty in such a case is to explain why one bud, or at any rate only a small proportion of the total number of buds, acts in this way when the circumstances of the case would appear to be substantially alike in all. To talk of the individuality of buds is to denote a fact which every observer must be conversant with, but which does not supply any explanation. In the second class of cases the flowers are, as in "hybrid perpetual" roses, placed at the ends of some of the shoots of the year. In this case gardeners have availed themselves of what was originally an occasional tendency to continue the development of flowers on the end of certain shoots, and have, as it were, converted an accidental into a constant occurrence. Doubtless they might do the same in the case of the laburnum, were they so disposed. It is here that the skill of the gardener comes in, and even enables him, to some extent, to baffle adverse climatic influence and induce a plant, as a regular thing, to flower twice in a season, or even more or less continuously, when, if left to itself it would either not do so at all, or only in a fitful, uncertain manner. It is worth notice, too, that these second blooms are often (but by no means invariably) malformed. Some rhododendrons now before me are so, while the double-flowered apples that one occasionally sees are always, in my experience, formed on the midsummer shoots of the tree. So, again, with pears, the second crop of flowers is usually produced on shoots of the year, and very generally the flowers are more or less imperfect or misshapen. The "Napoleon" pear behaves in this way every year. Every year, too, I am indebted to Mr. Burbidge, of the Trinity College Botanic Garden, Dublin, for specimens of "Bishop's Thumb" pears, produced on the summer shoots. These pears are more like fingers than thumbs, and are destitute of core. The flower-stalk swells up as usual, and produces an eatable pear, but the carpels and seeds are conspicuous by their absence. The developing force has been energetic enough to produce flower- and fruit-stalk, but it has failed in the more essential process of seed- and embryo-formation. Possibly in some cases the absence of seed may be the result of want of fertilisation. It may be that in the flowers some at least of the carpels are present with their contained ovules, but, owing to the want of effective fertilisation, they have dwindled away and left no trace.

It would be a curious and important matter to ascertain whether, and to what extent, this repeated flowering process exhausts the plant. If no seed were produced the extra outlay of energy would probably not be severely felt. But every rose-grower knows how great are his losses, and how difficult it is to keep his "standards" in good form and good health. Of course there are many causes for this, but it is not unreasonable to suppose that one of them arises from exhaustion from continuous flowering, which produces a condition that predisposes to disease.

Another phenomenon of a somewhat similar character is very commonly met with this autumn, although, not unnaturally, it does not attract so much attention. I allude to the production of buds and leaf-shoots on the partially withered stems of herbaceous perennial plants, such as various species of Epilobium, Malva, &c. The branches of these plants usually dry up after flowering, leaving only a rosette of leaves or a winter-bud to carry on the growth next season; but occasionally they retain some amount of vitality, and, as at this season, produce a new generation of shoots from the old ones.

These variations show how artificial are the distinctions denoted by the terms annual, perennial, herbaceous, and the like, and they show what a wide range of physiological diversity may exist within the limits of the same species. MAXWELL T. MASTERS

ARROW-RELEASE[1]

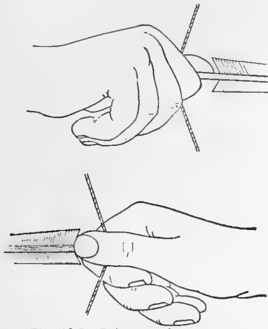
AT the commencement of this very interesting and instructive monograph, Prof. Morse tells us that when he began collecting data illustrating the various methods of releasing the arrow from the bow, as practised by different races, he was animated merely by curiosity; nor was it until he had accumulated quite a collection of sketches and other memoranda on the methods of arrow-release, not only of existing but of ancient races, as shown by frescoes and rock-sculptures, that he realised that even so trivial an art as that of releasing the arrow might possibly lead to interesting results in tracing the affinities of races. Hence he publishes in the present pamphlet the data which he has thus far collected, in the hope that further material may be secured for a more extended memoir on the subject. The great difference which Prof. Morse observed between the ordinary English and Japanese methods of using the bow first led him to investigate the subject, with the curious results to be presently narrated. The various forms of release, with their different modifications, are classified, and perhaps Prof. Morse's investigations may be most succinctly described by using his classification.

(1) *Ordinary Release.*—This is the simplest form of release, and is that which children all the world over naturally adopt in first using the bow. It consists in simply grasping the arrow between the end of the straightened thumb, and the first and second joints of the bent forefinger (Figs. 1 and 2). With a light or weak bow, says Prof. Morse, this release is the simplest and best; it makes little difference on which side of the bow the arrow rests, provided the bow is held vertically. On the other hand, however, a stiff bow cannot be drawn in this way, unless one possesses enormous strength in the fingers. This simple or primary release is that in use amongst the Ainos of Yezo, by the Demerara Indians, apparently also by the Utes. The Navajos employ it when shooting at prairie dogs, so that the arrow will not penetrate the ground if it misses its mark; so do the Chippewas. The Micmac Indians of the Cascapedia settlement, on the north shore of the Bay of Chaleur, used it, and it is said that the other tribes in this part of Canada draw the arrow in the same way. A member of the Penobscot tribe at Moosehead Lake, seemed incredulous when Prof.

[1] "Ancient and Modern Methods of Arrow-Release." By Edward S. Morse, Director Peabody Academy of Science. Essex Institute *Bulletin*, October-December, 1885.

Morse told him that there were other methods of drawing the arrow.

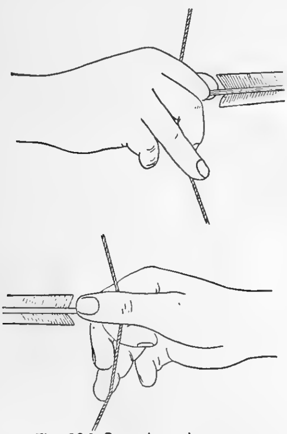
(2) *Secondary Release.*—This is a direct outgrowth from the primary release. It consists in grasping the arrow with the straightened thumb and bent forefinger, while the ends of the second and third fingers are brought to bear on the string to assist in drawing (Figs. 3 and 4).



Figs. 1&2. Primary release.

The Ottawas and Zuñi Indians practised this, as also did the Chippewas of Northern Wisconsin.

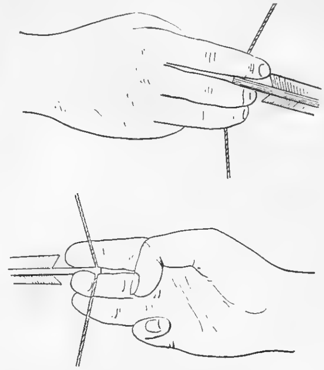
(3) The *Tertiary Release* differs little from the secondary. The forefinger, instead of being bent, is nearly straight, with its tip, as well as the tips of the second and third fingers, pressing or pulling on the string, the thumb, as in the primary and secondary release, active in assisting in pinching the arrow and pulling it back. This is used amongst various tribes of American Indians—Sioux, Araphoes, Cheyenne, Assinboins, Comanches,



Figs. 3&4. Secondary release.

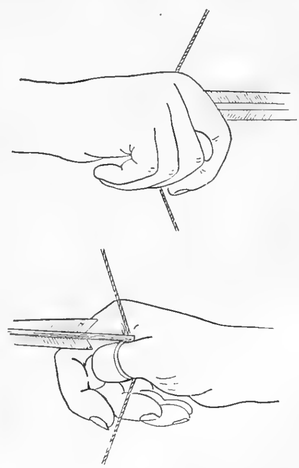
Crows, and Blackfeet. The Siamese, too, practise this release, with the difference that one finger only is used on the string instead of two. It appears, too, from Mr. Man's recent paper before the Anthropological Institute, that the Andaman Islanders use this method.

(4) *The Mediterranean Release.*—This release has been in vogue among the northern Mediterranean nations for centuries, and among those of the southern Mediterranean for tens of centuries, and is the oldest release of which we have any knowledge. It is practised to-day, continues Prof. Morse, by all modern English, French, and American archers, and is the release used by the European archers of the Middle Ages. It consists in drawing the string back with the tips of the first, second,



Figs. 5&6. Mediterranean release.

and third fingers, the balls of the fingers clinging to the string, with the terminal joints of the fingers slightly flexed. The arrow is held lightly between the first and second fingers, the thumb straight and inactive (Figs. 5 and 6). A leather glove or leather finger-strings are worn, as Roger Ascham expresses it in his "Toxophilus," published in 1584, "to save a man's fingers from hurtinge,



Figs. 7&8 Mongolian release.

that he may be able to beare the sharpe stringe to the uttermoste of his strengthe." In this release, the arrow must be to the left of the bow vertical. The Eskimo of Alaska employ this release, using, however, only the first and second fingers in drawing the string, and it appears to be almost universal in the Arctic regions.

These four releases may be considered, Prof. Morse thinks, as successive modifications of each other; but the next release is an entirely independent form, having no relation to the other.

(5) *The Mongolian Release.*—In this the string is drawn by the flexed thumb bent over the string, the end of the forefinger assisting in holding the thumb in position (Figs. 7 and 8). The arrow is held at the junction of the thumb and forefinger, the base of the finger pressing the arrow against the bow. For this reason the arrow is always placed to the right of the bow vertical. This release is characteristic of the Asiatic races, such as the Manchu, Chinese, Corean, Japanese, and Turk. The Persians also use it. The thumb is protected by a guard: the Manchus, Chinese, and others use a thick ring worn near the base of the thumb. It may be made of any hard material, such as horn, bone, ivory, quartz, agate, or jade. The Japanese archer uses a glove consisting of the thumb and two fingers.

These are the principal and most efficient forms of release, although doubtless there are others. Of the methods employed by ancient peoples, as represented in manuscripts, sculptures, &c., the Assyrians at one stage of their history appear to have used the primary form, while subsequently they used the secondary, and still later the Mediterranean release. The ancient Egyptians appear to have practised three, if not four, definite and distinct methods of release, but many of the representations in the old sculptures are evidently purely conventional, while some are clearly impossible. Following on these, Prof. Morse discusses the methods employed in ancient Greece, Persia, Japan, China, India, Mexico. Here he is naturally on less secure ground, for he has to endeavour to spell out a conclusion from various and conflicting positions of the hand in various ancient graphic representations of life amongst these peoples. The discussion involves a considerable amount of detail and numerous woodcuts by way of illustration, for which the reader must be referred to Prof. Morse's pamphlet. We must content ourselves with reproducing briefly his conclusions, which, it will be understood, are at present for the most part provisional, pending additional information and wider discussion. The persistence of a particular release in a people is well illustrated in the case of the Ainos. For centuries the Ainos have battled with the Japanese, and must have been mindful of the superior archery of their enemies; indeed, on all hands, with the exception possibly of the Kamchatdales to the north, the Ainos have been surrounded by races practising the Mongolian release, and yet have adhered to their primitive methods of shooting. The two strongest releases—both perhaps equally powerful—are the Mediterranean and Mongolian, and it is interesting to note that the two great divisions of the human family who can claim a history, and who have been dominant in the affairs of mankind, are the Mediterranean nations and the Mongolians. For several thousands of years each stock has had its peculiar arrow-release, and this has persisted through all the mutations of time to the present day. Language, manners, customs, religions, have in the course of centuries widely separated these two great divisions into nations. Side by side they have lived; devastating wars and wars of conquest have marked their contact; and yet the apparently trivial and simple act of releasing the arrow from the bow has remained unchanged. At the present moment the European and Asiatic archer, shooting now only for sport, practise each the release which characterised their remote ancestors. The following classified list shows in a general way that the primary, secondary, and tertiary releases are practised by savage races to-day, as well as by certain ancient civilised races, while the Mediterranean and Mongolian releases, though originating early in time, have always characterised the civilised and dominant races. The exceptions to this generalisation are curious: the Little Andaman Islanders practise the Mediterranean release, and those of the Great Andamans the Tertiary; various groups of Eskimo practise the Mediterranean release, and have designed a distinct form of arrow for this method.

Primary Release.—Savage: Ainos, Demerara Indians, various North American tribes; civilised: early Assyrian, Egyptian, and Grecian (?)

Secondary Release.—Savage: some North American tribes; civilised: later Assyrian and Indian (?)

Tertiary Release.—Savage: North American tribes, Great Andamans; civilised: Siamese, Egyptian, Grecian, and Mexican (?)

Mediterranean Release.—Savage: Eskimo, Little Andamans; civilised: European nations now, and the archers of the Middle Ages, later Assyrian, early Egyptian, Arabian, Indian, and Roman.

Mongolian Release. — Manchus, Chinese, Coreans, Japanese, Turks, Persians, Scythians, Egyptians (?)

In conclusion, Prof. Morse expresses a belief that the method of using the bow may form another point in establishing or disproving relationships, in identifying the affinities of past races. Travellers and explorers should not content themselves with observing the simple fact that such and such people use bows and arrows, but they should accurately record (1) the attitude of the shaft hand; (2) whether the bow is held horizontally or vertically; (3) whether the arrow is to the right or left of the bow vertical; and (4) whether the extra arrows are carried in the bow hand or shaft hand. The method of bracing the bow is of importance also. While anxious to get information respecting the arrow-releases of tribes and peoples, he is particularly desirous of hearing about those employed by the Veddahs of Ceylon, the hill-tribes of India, African tribes, and those of South America, especially the Fuegians. Such material, in the shape of descriptions, photographs, drawings, and if possible specimens of bows and arrows, may be sent to Prof. E. S. Morse, Peabody Academy of Science, Salem, Massachusetts, and will be acknowledged and used in a future publication on the subject.

CLIMATOLOGY OF THE CROYDON DISTRICT[1]

IN a little tract of thirty-six pages, which has just appeared in the *Transactions* of the Croydon Microscopical and Natural History Club, Mr. Eaton has discussed the climatology of this part of England with a skill, clearness, and fairness seldom met with in local climatologies. The observations of temperature, which were conducted on the same systematic plan with Stevenson's screens, were made at seven stations, these being, in the order of their heights, Park Hill, Addiscombe, South Norwood, West Norwood, Waddon, Wallington, and Beddington. The periods selected for discussion are the five years 1881 to 1885 inclusive. The stations are included within an area measuring 4 miles from north-east to south-west by $2\frac{1}{2}$ miles from south-east to north-west. The monthly results are given on fourteen pages with satisfactory fullness; and with them are conjoined, for the sake of comparison, the corresponding records of temperature at the Greenwich and Kew Observatories.

The heights and mean temperatures of the five stations from which observations are available for the whole of the five years are these:—Beddington, 102 feet, 48°·8; Waddon, 156 feet, 49°·0; South Norwood, 190 feet, 49°·4; Addiscombe, 202 feet, 49°·3; and Park Hill, 259 feet, 49°·4,—Park Hill, the highest station, being thus 0°·6 warmer than Beddington, the lowest station. This subversion of the general rule that the temperature diminishes with greater elevation is shown to be due to the frequency with which, on clear calm nights, the air in contact with the ground is cooled and rendered denser by radiation,

[1] "Report on the Temperature and the Rainfall of the Croydon District, 1881-85," by Henry Storks Eaton.

and thereafter descends to the low-lying grounds of the valleys, displacing the warmer air below. During the unusually dry clear months of January and July 1881 the mean temperature of Park Hill exceeded that of Beddington by 3°·5 and 2°·5 respectively. Hence the first three of the five stations which are on sloping ground have, though at greater elevations than the other two stations below, higher mean temperatures.

This peculiarity in the distribution of the night and the winter temperature becomes the more intensified as the valley is deeper and its sides steeper, and as calms and light winds prevail. Thus at Klagenfurt, situated in one of the valleys of the Tyrol, the mean temperature of January is 20°·7, whereas at the station of Obergipfel, about seven miles distant and 4270 feet higher, the mean for the same month is 19° 9, being thus less than a degree lower than that of Klagenfurt. The subject is one that has seldom received the earnest attention it deserves, particularly in drawing the isothermals of the globe. The Croydon Club would make a clear addition to their observing-system if new stations were established on knolls in the valley of the Wandle for the further prosecution of this inquiry.

The means of temperature from Greenwich and Kew would have had real value in this inquiry if Mr. Eaton could have availed himself of observations made at these Observatories with thermometers exposed in the Stevenson screen. But, as pointed out, the different modes of exposing the thermometers render the results of the three systems of observing incomparable *inter se.* Thus the mean of the daily highest temperature of August for the five years is 72°·5 for Greenwich, and 69°·5 for Kew.

The rainfall has been far more extensively observed in the district, the returns of no fewer than seventy stations being available. Grouping the stations according to height, the annual amounts at stations below 200 feet show a mean of 23·27 inches; 200 to 400 feet, 25·39 inches; 400 to 600 feet, 29·12 inches; 600 to 800 feet, 31·66 inches; and above 800 feet, 31·36 inches. The largest amounts of rain occur not on the ridge of the North Downs, but some distance on the lee-side in regard to the prevalent rainy south-westerly winds; and the amount at like elevations seems also to diminish from west to east. As regards the monthly rainfall, the depth is greater in the upper groups; but the ratios of the monthly to the annual fall show that in spring, but more particularly in summer, there falls proportionally a larger amount of rain in the lower group of stations, whose average elevation is 193 feet. The relatively large increase in the summer rainfall over low-lying plains is one of the most striking facts in the geographical distribution of the rainfall, and is probably due to the physical causes concerned in the development of thunderstorms.

NOTES ON THE RECENT SWARMING OF APHIDES

THE immediate cause of the sudden appearance of clouds of insects in certain localities is not very apparent, but it may be surmised that the predominance or scarceness of their natural insect foes has much control over the phenomenon; added to which must be taken into account the effects of weather and temperature. A few days ago I had a notice from an obliging Birmingham correspondent, Mr. George Baker, who kindly furnished me with the following particulars:—

On October 5 the town of Mansfield, on the borders of Sherwood Forest, was visited by a cloud of Aphides, which swarmed in the town and over the country round, across an area of many miles. The town was visited "literally by millions; every one, as they walked along, waving their handkerchiefs or newspapers before their faces to avoid inhaling the insects. . . . Wet paint was covered by a mass of these black Aphides." This swarm continued with decreasing numbers throughout five days, and heavy rain during part of this time did not seem much to affect them. On the road to Nottingham these insects were noticed as engaged in singular gyrations and undulatory dances above the tops of the spruce-firs, there forming dense pyramidal columns.

A similar cloud, but less remarkable as to numbers, was observed about the same time at Birmingham; which, however, as the town must be at least 50 miles distant, can be scarcely considered as forming a part of this same swarm. Possibly similar causes operated to produce the like phenomenon in both places.

These insects proved on examination to be *Rhopalosiphum dianthi* of Schrank, which is identical with *Aphis persicæ* of Morren, and *A. rapæ* of Curtis, and *A. vastator* of Smee. It is a veritable pest in some years, doing considerable damage to turnip, mangel, and other crops, and in our gardens injuring our peach-trees. This present notice of its swarming is, however, by no means unprecedented.

In September and October 1834 Morren noted an immense swarm all over Belgium, and states his belief that it came across the sea from England. He says they obscured the light of day, and covered the walls of the houses so as partially to conceal them. Gilbert White notes that in August 1785 the people of Selborne were surprised by a swarm of "smother flies." Those that were walking in the street found themselves covered with these insects, which blackened the hedges and vegetables round. White thought these might be emigrations from the hop-gardens of Kent and Sussex, and from those near Farnham. If so, the species differs from the insects above noticed.

The choice of high objects to dance over is not confined to Aphides, *e.g.* many of the Tipulidæ. The singular persistent dance of *Anthomyia meteorica* over the heads of horses is familiar to all. G. B. BUCKTON

NOTES

A MOST attractive group of birds has just been placed by Prof. Flower in the great hall of the Natural History Museum at South Kensington. The case is intended to illustrate the hybridisation of species in a state of nature, and the species selected are the hooded and carrion crows (*Corvus cornix* and *C. corone*) and the European and Asiatic goldfinches (*Carduelis elegans* and *C. orientalis*). The series of these birds has been presented to the Museum by Mr. Henry Seebohm, who procured the specimens himself during his travels in Siberia. The case of the crows is one of the few instances known of actual wild hybridisation, though many more are suspected, especially among the game birds. It is certain, however, that wherever the colonies of hooded crows meet the carrion crow throughout the Palæarctic region the two species interbreed freely, and the result is shown in the young, the gray saddle-back of the hooded crow exhibiting a considerable admixture of black owing to the strain of *C. corone* in the parentage. The case of the goldfinches is not quite so completely proved, but is apparently a parallel instance of hybridisation. The British Museum has been for some time indebted to Mr. Seebohm for very valuable presents of birds, which have been mounted in the bird-galleries. Not long ago he gave a specimen of Ross's gull (*Rhodostethia rossi*), one of the rarest of the *Laridæ*, and a species which was a *desideratum* to the national collection. He presented also, last year, a fine case of Steller's sea-eagle (*Haliaëtus pelagicus*) from Kamchatka.

THE Geodetic Conference began its meetings in Berlin last week. The countries represented are Belgium, by two delegates; Denmark, by one; Germany, by fourteen, including Prof. Dr. Förster, of the Royal Observatory, Prof. Helmholtz, Dr. W. Siemens, and Colonel Golz, of the Trigonometrical Survey: France, by two, namely, MM. Faye and Tisserand; Italy, by one; the Netherlands, by one; Norway, by one; Austria, by three; Portugal, by one; Roumania, by two; Russia, by two, including Dr. von Struve, of the Observatory at Pulkowa; Sweden, Switzerland, and Spain, each by one. England, strange to say, is not represented; nor has any one come from the United States. Prof. Dr. Förster, of Berlin, was elected President, and Dr. von Struve, of Pulkowa, Vice-President of the Conference. In his opening address, Herr von Gossler, Prussian Minister of Public Worship, indulged in some general observations as to the progress and aims of geodetic science, and, in the name of the Prussian Government, thanked the various foreign deputies for their appearance in Berlin. The chief task of the present Conference has been to settle the organisation of the central geodetic bureau, which is to have its permanent seat in Berlin, in connection with the Geodetic Institute of Prussia, founded by the late Lieut.-General von Bäyer. It was at the instance of Lieut.-General Bäyer that the first constituent international meeting of geodetic experts was held in Berlin in 1864, and it is by the establishment of a central international bureau here, supported by quotas from the various countries which it represents, that it is intended to preserve to Prussia the leading part she has always taken in promoting the science of earth-measuring and all its kindred branches. The permanent Committee elected includes Prof. Hirsch, of the Neuchâtel Observatory (Secretary), Professors Förster (Prussia), Sande (Holland), Faye (France), Ferrero (Italy), Ibannez (Spain), Ragel (Saxony), Oppolzer (Austria), Stepnicki (Russia), and Zachariae (Denmark). The next Conference will be held in 1887 at Nice, on the invitation of M. Bischoffsheim, owner of the great Observatory there. Before separating, the Conference passed a resolution requesting the Prussian Government to invite other States to join the International Geodetic Society.

At a recent meeting of the Common Council it was decided that it be referred to the Gresham Committee to consider whether the moneys now paid for lectures under the provisions of Sir Thomas Gresham's will might be devoted to the encouragement of students destined for commercial careers acquiring a useful knowledge of modern languages, with instructions to confer with the Mercers' Company, and to report thereon forthwith.

The Professor of Physics of the University of Vienna, Dr. Victor Pierie, died suddenly of appoplexy in his laboratory on Friday last.

At the Potato Centenary on December 2 and 3, to which we have already referred, the following subjects for conferences have been proposed:—First day, Morning: (1) historic consideration of the question, Whence came the potato to England? (2) the Incas and their cultivation of the potato; (3) distinct wild species of the potato as at present recognised; (4) the production of varieties by cultivation. Afternoon: (5) the potato disease; (*a*) historic sketch, (*b*) our present knowledge of the disease. Second day, Morning: (1) proposed methods for preventing the disease; (2) methods for using partly diseased potatoes; (3) methods for storing and preserving potatoes. Afternoon: conference of cultivators on rates for transport of potatoes.

The French Government has granted the funds required for the completion of the Algiers Observatory, which will be in full operation next spring. Two assistant astronomers have already been sent to join M. Trépied, and two others will be selected from among the pupils of the School of Astronomy this winter. A special Congress will be held in Paris, in the month of April, for determining the part that the Algiers Observatory will take in stellar photography. The direct image of the sun will be 6 centimetres in diameter. A spectroscope by Thollon will be put into operation. The extent of the spectrum will be 10 metres. M. Trépied has organised the electrical transmission of the time to the Hôtel de Ville of Algiers and Tunis. Colonel Perrier, head of the French and Algerian Survey, is arranging the measurement of the requisite triangles for connecting the Algiers Observatory with the Colonne Voirol, the starting-point of the Algerio-Tunisian system of triangulation.

Mr. W. A. Carter, of the Colonial and Indian Exhibition, writes to us that during this last spring he placed a specimen of the Mexican axolotl in an empty (? dry) receptacle, where it has remained ever since. It is in a lively condition. The colour of the animal has become less intense, the gills have apparently disappeared, and the powers of locomotion seem quickened.

It is worthy of note that at the establishment of the National Fish Culture Association many of the brook trout (*Salmo fontinalis*) hatched during February 1885 commenced to spawn last week, yielding about five hundred ova each. This fact is another proof of the extraordinary reproductive capacity of fishes in spite of age and artificial existence, for the fish in question have been maintained in a pond of limited dimensions. The size of the ova is small as compared with those of mature fish, therefore it is not likely that the trout when hatched will be large. The parents are in a healthy condition, and seem in no way weakened.

A consignment of nearly a thousand German carp of various kinds has arrived at the Colonial and Indian Exhibition. The great hardihood of the carp is evidenced by the fact that the fish in question were retained in carriers for sixty hours before being placed in tanks, when only two were found to have succumbed.

In a paper in the October number of the *American Journal of Science* by Mr. O. W. Huntington, "On the Crystalline Structure of Iron Meteorites," the author concludes as follows:—"We have tried in this paper to establish the following points: (1) that many of the masses of meteoric iron in our collections are cleavage crystals, broken off probably by the impact of the mass against the atmosphere; (2) that these masses show cleavages parallel to the planes of all the three fundamental forms of the isometric or regular system, namely, the octahedron, the cube, and the dodecahedron; (3) that the Widmanstättian figures and Neumann lines are sections of planes of crystalline growth parallel to the same three fundamental forms of the isometric system; (4) that on different sections of meteorites Widmanstättian figures and Neumann lines can be exhibited in every gradation, from the broadest bands to the finest markings, with no break where a natural line of division can be drawn; (5) that the features of the Widmanstättian figures are due to the eliminations of incompatible material during the process of crystallisation. This investigation throws no new light upon the origin of meteorites, except so far as it strengthens the opinion that the process of crystallisation must have been extremely slow. The occurrence of large masses of native iron occluding hydrogen gas, and containing nickel, cobalt, phosphorus, sulphur, &c., implies a combination of conditions which the spectroscope indicates as actually realised in our own sun and in other suns among the fixed stars, and the most probable theory seems to be that these masses were thrown off from such a sun, and that they very slowly cooled, while revolving in a zone of intense heat. In this paper we have not taken into consideration a number of iron masses, whose meteoric origin has been generally accepted, which show no Widmanstättian figures, and not even any Neumann lines. A considerable proportion of these are certainly not meteoric. In the Harvard cabinet there are two specimens, labelled respectively Campbell County (Tennessee), and Hominy

Creek (North Carolina), which are evidently nothing but cast-iron, and a third, labelled Tarapaca Hemalga (Chili), which is probably of similar material. We could find on the specimens of this class in the Harvard collection no distinct evidences of crystallisation; but also we could find no features incompatible with that unity of structure which it has been the chief object of this paper to illustrate."

Mr. Horatio Hale has issued in pamphlet form his address "On the Origin of Languages and the Antiquity of Speaking Man," delivered before the Anthropological Section of the American Association for the Advancement of Science at Buffalo last August. The author's views were much discussed at the time, and those interested in the subject will be thankful to have them presented in this convenient form. Rejecting all the theories hitherto advanced by Lyell, Frederick Müller, and others, he endeavours to account for the vast number of *specifically distinct* languages spoken by races *not specifically distinct* by assuming that they originated from children's prattle in independent centres after the spread of speechless man over the globe. The cases are mentioned of the Boston twins born in 1860 and of some other "Geschwister," who appear to have evolved and practised for some time infantile jargons understood only amongst themselves, which it is argued might, under favourable conditions of isolation and so forth, develop into regular forms of speech consistently worked out with their own vocabularies and grammatical structure. In this way linguistic families differing absolutely one from the other need not be of any great antiquity, and in fact may have been developed from slight germs in many places and at different times since the dispersion of the "*homo alallus*" from some given centre. This *homo alallus* himself is admitted to be the lineal descendant of the men of the Stone Age, who are assumed to have been speechless, so that all forms of speech now current may be of comparatively recent date, say, not more than 8000 or 10,000 years, notwithstanding their great number and profound differences. This theory, which refers human speech in the first instance to "the language-making instinct of very young children," is presented with considerable force and plausibility, but will scarcely be taken seriously either by philologists or anthropologists. The latter especially will find it difficult to accept the conclusion that man properly so called, the *homo sapiens*, as distinguished from his precursor of the Neolithic Age, does not date further back than "somewhere between 6000 and 10,000 years ago." The theory also requires us to regard this first speaking man as already fully developed, possessing "intellectual faculties of the highest order, such as none of his descendants has surpassed," thus reversing the conclusions of modern anthropology.

It is reported from Vienna that a great ice cavern has been discovered on the southern slope of the Dachstein, or Schneeberg, the very conspicuous lofty mountain in Lower Austria, which is visible from the ramparts of the capital. The general direction of the cavern runs from south to north, and it has been explored for a distance of 600 metres, a sharp precipice seemingly 14 metres deep having stopped for the time further progress. The cavern is from 5 to 6 metres broad, and very lofty, giving the impression that the ice is enormously thick. The explorers are of opinion that a subterranean lake will be found in the cavern.

The additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus* ♀) from India, presented by Miss Edith Prowse; four Common Hedgehogs (*Erinaceus europæus*), British, presented by Mr. W. Walkinshaw; a —— Buzzard (*Buteo* ——) from Mogador, North Africa, presented by Mr. P. L. Forwood; a Ring-necked Parrakeet (*Palæornis torquatus* ♀) from India, presented by Mr. W. S. Bradshaw; an Aldrovandi's Skink (*Plestiodon auratus*) from North Africa, deposited; a Rusty-spotted Cat (*Felis rubiginosa*) from Ceylon, two Diuca Finches (*Diuca grisea*) from Chili, two Wood Larks (*Alauda arborea*), British, purchased; eight Long-fronted Gerbilles (*Gerbillus longifrons*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

The Binary Star γ Coronæ Australis.—Mr. H. C. Wilson, of Cincinnati Observatory, has published elements of the orbit of this interesting southern double star in the *Sidereal Messenger* for October. These elements, which do not differ much from a set recently computed by Mr. Gore (*Monthly Notices*, vol. xlvi. p. 104), are as follows:—

P = 78·80 years	λ = 139°·0
T = 1887·40	☊ = 41°·0
e = 0·324	a = 1″·85
γ = 50°·5	

Comparing observations made 1834·47 to 1883·62 with this orbit, Mr. Wilson finds that the position-angles are well represented, with the exception of those observed by Powell from 1859 to 1864, which seem to be affected by systematic error, and thinks we may conclude the period is not far from eighty years. It is to be hoped that numerous observations of this star will be obtained during the next ten years, while the distance is small and the angular motion rapid.

Oppolzer's Astronomical Refractions.—Herr Oppolzer has recently published, in the *Transactions* of the Mathematical and Natural Science Section of the Imperial Academy of Sciences of Vienna, vol. liii., a paper containing a theoretical discussion of the problem of astronomical refraction, followed by numerical tables intended to facilitate the practical application of the results at which he arrives. The relation between the temperature (t) and density (ρ) of the atmosphere which Herr Oppolzer adopts is

$$\frac{\delta t}{\delta \rho} = \epsilon + \Sigma k \rho^{\sigma - 1},$$

where k and σ are quantities depending on the state of the atmosphere and on the place of observation. Whatever may be thought of the legitimacy of a relation of this form from a theoretical point of view, it at all events has the advantage, in Herr Oppolzer's skilful hands, of leading to a comparatively simple expression for the amount of refraction, deduced from a modification of the ordinary differential equation. And that it is capable, when the approximations are carried far enough, of giving results of great accuracy for large zenith distances, is shown by a comparison made between the computed values of the refraction and the well-known observations of Argelander, which form the basis of Bessel's supplementary table given in the "Tabulæ Regiomontanæ," with the following results:—

Z.D.	Observed—Computed	Z.D.	Observed—Computed

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 *NOVEMBER* 7–13

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on November 7

Sun rises, 7h. 6m.; souths, 11h. 43m. 49·6s.; sets, 16h. 22m.; decl. on meridian, 16° 21′ S.: Sidereal Time at Sunset, 19h. 29m.

Moon (Full on November 11) rises, 15h. 4m.; souths, 20h. 58m.; sets, 3h. 2m.*; decl. on meridian, 1° 49′ S.

Planet	Rises	Souths	Sets	Decl. on meridian
	h. m.	h. m.	h. m.	° ′
Mercury	9 22	13 11	17 0	23 59 S.
Venus	6 26	11 20	16 14	13 25 S.
Mars	10 42	14 27	18 12	24 27 S.
Jupiter	4 55	10 19	15 43	7 43 S.
Saturn	20 30*	4 32	12 34	21 18 N.

* Indicates that the rising is that of the preceding evening and the setting that of the following morning.

Occultations of Stars by the Moon (visible at Greenwich)

M signifies maximum; *m* minimum.

Meteor Showers

A radiant near δ Hydræ, R.A. 124°, Decl. 4° N., and one in Camelopardus, R.A. 102°, Decl. 73° N., are active in the early part of this week. Moonlight interferes with meteor observation during the greater part of the week.

THE HIGH TEMPERATURE IN OCTOBER

THE warm weather which occurred at the commencement of the month was so exceptional for the season, and extended over so large a part of Europe, that a few facts as to its general character may be of interest, and will afford opportunity of comparison with earlier records, as well as with records of any similar weather in time to come.

The highest temperatures were experienced during the first five days of the month, and were chiefly confined to Western, Central, and Southern Europe. During this time atmospheric pressure was generally high over Central Europe, and decreased towards the western or Atlantic coasts, so that the conditions of pressure were favourable to anticyclonic circulation over France and the south-east of England, and cyclonic circulation in Ireland and the northern parts of the British Islands. The barometric gradients were very slight over the Continent, but were rather steeper over Great Britain and Ireland, owing to the proximity of a barometric depression to the westward. This distribution of pressure was accompanied by southerly and south-easterly winds over Western Europe, and especially over France and our own islands, but it was only in Ireland and the more western parts of Great Britain that the wind was at all fresh.

At this season of the year our warmest weather in England is commonly experienced with south-easterly winds, as is well shown in the valuable discussion of the Greenwich observations for the years 1849 to 1868, in which the temperatures have been averaged for the several wind directions. The following are the temperatures for October:—

	N.	N.E.	E.	S.E.	S.	S.W.	W.	N.W.
Monthly means	47	50	52	55	53	53	51	51
Highest hourly means	52	55	59	61	59	58	57	55

The same discussion also shows the striking difference which exists, in October, between the temperature with a cloudless and a cloudy sky:—

	Mean	Mean max.	Mean min.
Cloudless sky	50·8	61·1	43·5
Cloudy sky	51·8	54·8	49·8

The high temperatures experienced over England in October this year occurred with an exceptionally clear sky, as well as with a remarkably steady south-easterly wind, and the air before reaching England had been subjected to very similar conditions on the continent of Europe.

The following table gives the *maximum* day temperatures at twenty stations selected from the Daily Weather Report of the Meteorological Office and from the Paris *Bulletin International* for the first five days of October:—

	Station	Day 1	2	3	4	5	Mean
		°	°	°	°	°	°
British Islands	York	64	63	66	69	63	65
	Greenwich	78	68	69	79	77	74
	Parsonstown (Ireland)	58	61	61	64	66	62
France	Dunkirk	79	72	72	81	79	77
	Cherbourg	72	73	64	72	68	70
	Paris	77	65	78	78	77	75
	Nantes	79	70	81	82	64	75
	Biarritz	82	73	81	81	68	77
	Nice	72	73	75	77	75	74
Germany	Hamburg	61	68	61	64	68	64
	Berlin	63	73	63	61	66	65
	Carlsruhe	75	70	75	72	70	72
Belgium	Brussels	76	64	71	75	77	73
Austria	Vienna	73	75	73	72	70	73
Spain and Portugal	Barcelona	88	100	95	91	85	92
	Madrid	62	72	75	70	68?	69
	Lisbon	70	68	68	70	68	69
Italy	Turin	72	73	73	73	73	73
	Rome	77	79	81	81	81	80
	Palermo (Sicily)	82	84	84	82	84	83
	Mean	73	72	73	75	72	

The stations have been selected as representative of Western, Central, and Southern Europe, and the table shows well the area over which the warm weather extended.

The more northern parts of Europe did not experience any exceptional heat, the highest temperature at Copenhagen being 63°, and at Stockholm 61°. The more western parts were also but little affected: in Ireland the highest maximum was 66° at Parsonstown on the 5th, and at no other station was the temperature above 65°. In Scotland the temperature did not reach 70°.

The Greenwich observations from 1841 show that a higher temperature has only once been registered in October, viz. 81° on the 4th in 1859; but the daily mean, which was 67°·1 on the 4th this year, is higher than any previously recorded.

The observations which were made in the apartments of the Royal Society from the year 1794, excepting the years 1811 to 1819, do not show so high a reading between 1794 and 1840. At Kew Observatory the highest temperature recorded was 77°

on the 4th, and this is the highest ever observed in the month of October; on the 5th, 76° was registered, which corresponds with the temperature observed on October 4, 1859. The returns of the Meteorological Office show that 80° was observed on the 4th in London and at Cambridge, whilst 77° was registered at several stations in the east of England and in the Midland Counties.

It is difficult to make any satisfactory comparison with previous records, except at one or two places, but these tend to show that so high a temperature at this season does not occur more than about twice in a century. CHAS. HARDING

VOLCANOES OF JAPAN

THE last number (vol. ix. part 2) of the *Transactions* of the Seismological Society of Japan is wholly occupied by a paper of Prof. Milne's, on Japanese volcanoes, which is the longest contribution that has yet appeared in the Society's *Transactions*. The paper is partly historical and partly scientific, and contains, so far as the writer has been able to collect, references to everything that is known on the subject. Very much comes from his own observations, for he has travelled over the greater part of Japan, and has ascended many of the volcanoes. The paper also contains an epitome of some thirty or forty works in Japanese. On the whole, it is a systematic account of material which has been accumulating for the last eleven years.

The following are the more important conclusions which Prof. Milne has formulated in the paper :—

1. *Number of Volcanoes.*—As Japan has not yet been completely explored, and, moreover, as there is considerable difficulty in defining the kind of mountain to be regarded as a volcano, it is impossible to give an absolute statement as to the number of volcanoes in the country. If under the term volcano be included all mountains which have been in a state of eruption within the historical period, those which have a true volcanic form, together with those which still exhibit on their flanks matter ejected from a crater, we may conclude that there are at least 100 such mountains in the Japanese Empire. If to this list be added the ruins and basalt wrecks of volcanic cones, the number would be considerably increased. These mountains are distributed as follows :—

Northern Region	Kuriles	23
	Yezo	28
Central Region	Northern main island, Central ,, ,, Oshima group	35
Southern Region	Southern main island	1
	Kiushiu, Southern islands	13
	Total	100

Of this number about 48 are still active, or have been so during the historical period. These active volcanoes are distributed as follows :—

Northern Region	Kuriles 16, Yezo 11	27
Central Region		12
Southern Region		9
	Total	48

From this it will be seen that volcanic activity in Japan decreases from the north towards the south.

2. *Number of Eruptions.*—Altogether about 232 eruptions have been recorded, and of these the greater number took place in the southern districts. This may perhaps be accounted for by the fact that Japanese civilisation advanced from the south. In consequence of this, records were made of various phenomena in the south when the northern districts were still unknown and unexplored regions. The greater number of eruptions took place in February and April. Comparing the frequency of eruptions in the different seasons, the volcanoes of Japan appear to have followed the same law as the earthquakes, a greater number having taken place during the cold months. This winter frequency of volcanic eruptions may possibly be accounted for in the same manner that Dr. Knott accounted for the winter frequency of earthquakes. During the winter months the average barometric gradient across Japan is steeper than in summer. This, coupled with the piling up of snow in the northern regions, gives rise to long-continued stresses, in consequence of which certain portions of the earth's crust are more prepared to give way during the winter months than they are in summer.

3. *Position and Relative Age of Japanese Volcanoes.*—The youngest of the Japanese volcanoes appear to be those which exist as, or on, small islands. On the islands in the Kuriles, in the Oshima group, and in the Satsuma sea, many of the volcanoes are yet young and vigorous. Moreover, many of these islands have been formed during the historical period. The island-forming period in the Satsuma sea, for example, was about the year 1780.

The volcanoes of Japan form a long chain running from N.E. towards S.W.; but a closer examination of the distribution of the volcanic vents shows that there are probably four lines :—

(*a*) The N.E.-S.W. line running from Kamchatka through the Kuriles and Northern Yezo.

(*b*) The curved line following the backbone of the main island, and terminating on the western side of the Yezo anticlinal.

(*c*) The N.N.W.-S.S.E. line of the Oshima group. This line, coming from the Ladrones, passes through Oshima and Fujisan parallel to and near to the line of a supposed fault. Here it intersects the main line running through the main island. Volcanic vents are here very numerous. As the main island line is intersected, while the Oshima line is the intersector, it may be argued that the Oshima-Fujisan line of volcanoes are younger than many of those on the main island line.

(*d*) The Satsuma line, coming from the Philippines through Sakurajima and culminating in the famous Mount Aso, which is the nucleus of Kiushiu.

4. *Lithological and Chemical Character of Lavas.*—Although Prof. Milne has made an extensive collection of the volcanic rocks of Japan, the opportunity for examining them has not yet presented itself, and therefore he can only speak of them in general terms. They are at present being carefully studied by the officers of the Geological Survey. The rocks in his possession are chiefly andesites. Those containing augite, like the rocks of Fujisan, closely approximate to basalts. True basalt is, however, rare. Another common rock is hornblende andesite, some of which contains free quartz. Quartz trachytes occur in the north of Japan. The following table shows the percentages of silica, and ferrous and ferric oxide, contained in the rocks of ten volcanoes :—

Locality.	SiO_2	FeO	Fe_2O_3
1. Norokura	61·72	1·35	3·50
2. Misake	59·97	3·27	3·86
3. Kusatsu	61·49	3·30	4·35
4. Amagi (Hakone)	65·34	2·45	3·09
5. Komagadake	56·27	2·19	6·69
6. Moriyoshi	59·17	2·65	4·15
7. Chokai	60·64	3·81	3·14
	54·55	5·19	4·42
8. Hakone (Tonosawa)	48·97	4·02	4·81
9 Fujisan	49·00	5·1	6·06
10. Oshima	52·00	13·70(?)	

One feature exhibited by the table is that the rocks of Oshima, Fujisan, and Tonosawa are basic, while those like Chokaisan and Moriyoshiyama belonging to the line of volcanoes of the main island, are relatively acidic. More extended observations of this description may show that different lines of volcanoes have thrown out different lavas, or that the lavas of different constitution are of different ages.

5. *Magnetic Character of Rocks.*—In a study of the soils in the neighbourhood of Tokio, Mr. E. Kinch refers specially to the magnetite they contain. A great portion of this comes from the disintegration of volcanic rocks. Many of the Japanese lavas have a distinct effect upon a compass needle, and many of the black lavas from the crater of Fujisan will easily turn the needle of an ordinary compass through 360°. Many of the pieces of lava are not only magnetic but polar. Dr. Naumann found a block of augite trachyte on the top of Moriyoshiyama which would deflect the needle of a compass through 155°. The most curious observation made by this investigator was that the magnetic declination near Gaujusan has during the last eighty years (when it was about 14° 30′ E.) decreased 19°, being now about 5° W. As we recede from this mountain the amount of

change is less. Assuming this result to be correct, it would seem justifiable to look to Gaujusan as connected with these local changes. Some of the volcanoes in the Kuriles are said to exert a marked influence upon the compasses of ships. When a vessel is lying near certain mountains, as, for instance, in Bear Bay at the north end of Iturup, a distant mountain will have a very different bearing to that which is indicated by the same compass when the vessel is a short distance outside Bear Bay. In both cases the ship may be lying in the same direction, and the direction of observation is practically along the same line. This leads Prof. Milne to urge, as he has already done, that a magnetic observatory should be placed on or near one of the nine active volcanoes of Japan. Changes in volcanic activity are probably accompanied by local changes in the magnetic effects produced by subterranean volcanic magmas. These changes may be due to alterations in position, alterations in chemical constitution, and changes due to the acquisition or loss of heat. If such is the case, he argues, the records of a magnetic observatory would lead up to a knowledge of the changes taking place beneath the ground. When it is remembered that volcanoes like Oshima (Vries Island), where it seems probable that there may be local and rapid changes in magnetic variation taking place, lie in the track of so many vessels, the proposed investigation has a practical as well as a scientific aspect. An investigation of earth-currents at and near volcanoes might be added to the magnetic investigations.

6. *Intensity of Eruptions.*—It appears from the accounts of eruptions which are given in the paper that the intensity of volcanic action in Japan has been as great as in any other part of the world. One period of unusual activity was between the years 1780 and 1800, a time when there was great activity elsewhere in the globe. It was during this period that part of Mount Unsen was blown up, and from 27,000 to 53,000 persons (according to different accounts) perished, that many islands were formed in the Satsuma sea, that Sakurajima threw out so much pumice material that it was possible to walk a distance of 23 miles upon the floating *débris* in the sea, and that Asama ejected so many blocks of stone—one of which is said to have been 42 feet in diameter—and a lava-stream 68 kilometres in length.

7. *The Form of Volcanoes.*—The regular so-called conical form is very noticeable in many of the Japanese mountains, especially perhaps in those of recent origin. Outlines of these volcanoes, as exhibited either by sketches or photographs, show curvatures which are similar to each other. From a collection of photographs Prof. Milne traced the profiles of a number of important mountains in Japan. These are reproduced in the paper (see Fig. 1). From an examination of these figures he found that the

FIG. 1.—Outline of Fujiyama, from a photograph. This may be taken as typical of many Japanese volcanoes.

curvature of a typical volcano was logarithmic, or, in other words, the form of such a mountain was such as might be produced by the revolution of a logarithmic curve round its asymptote. In his original paper on the subject he said that the form agreed with that which would be produced by the piling up of loose material. He ought to have said it was the form assumed by a self-supporting mass of coherent material. Mr. George F. Becker (*American Journal of Science*, October 1885) continues these observations by an analytical investigation of the conditions of such equilibrium. If the height of a column is a, its radius y, the distance of any horizontal plane from the base x, the specific gravity of the material ρ, and the co-efficient of resistance to crushing at the elastic limit k, then the equation of the curve, which by its revolution about the x axis will generate the finite unloaded column of the "least variable resistance" is—

$$\frac{y}{c} = \frac{e^{-\frac{x}{c}} - e^{\frac{x}{c}}}{2},$$

where

$$c = \frac{2k}{\rho}.$$

This latter quantity is of course different for different materials. It can be expressed in terms of x and y—

$$\frac{2k}{\rho} = \frac{y}{(\tan^2 d - 1)^{-\frac{1}{2}}},$$

d being the angle which the tangent at any point makes with the x axis. The value of c can be obtained from photographs or drawings of a mountain, while ρ may be obtained from pendulum experiments or from specimens of volcanic material. With these data we can determine the modulus of resistance at the elastic limit of the materials which compose a mountain on a large scale for many constituents of the earth's crust. Mr. Becker concludes his observations by remarking that a study of the form and dimensions of lunar volcanoes would lead to values of $\frac{k}{\rho}$, from whence we might approximately determine whether the lunar lava is similar to that of terrestrial origin. In the table which follows, Prof. Milne has followed out Mr. Becker's suggestion, and calculated the modulus of resistance to crushing at the elastic limit in pounds per square foot for a number of Japanese mountains. The different values for $\frac{2k}{\rho}$ for the same mountain is in great measure due to the absence of an accurate scale for the various photographs which had to be investigated. Another difficulty was obtaining a value for r, or the density of the mountain. Prof. Mendenhall, who made a number of experiments with pendulums on the summit of Fujisan, says the rocks of that mountain have a density of 1·75. This is when they have air in their pores. As powder the density becomes 2·5. Wada gives the specific gravity of the rock on Fujisan as 2·6.

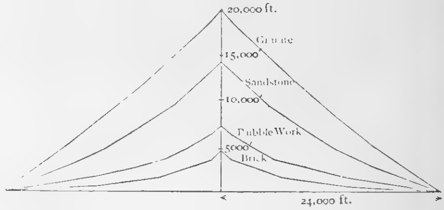

FIG. 2.—Theoretical Mountains.

Assuming the density of the earth at 5·67, then the density of Fujisan, as determined by Prof. Mendenhall's experiments, is 2·08. In the following table the density of the materials of all the mountains mentioned is taken at 2·5.

	Height in feet	$\frac{2k}{\rho}$	$\frac{k}{\rho}$	Load in lbs. per square foot	
Fujisan	12,441	4200	...	...	Photograph
	...	5000	...	...	,,
	...	4240	...	...	,,
	...	3500	...	...	,,
	...	{5420 5450}	...	...	,,
	...	5440	...	...	,,
	...	{3945 4133}	...	...	,,
	..	4430	...	...	Surveyed section
	...	3640	...	...	,, ,,
Average for Fujisan	...	4490	2245	350,220	,, ,,
Iwakisan	5260	2360	1180	174,080	Photograph
Nantaisan......	3800[1]	2000	1000	156,000	,,
Alaid..	7773	{2195 2120}	1078	163,168	,,
Krakatão	2745 ...	{1310 1310}	655	102,180	Surveyed section

Comparing the results given in the above table with the numbers given in the next section, which are based on experi-

[1] This is the height above Lake Chuzenji.

ments referred to in Rankine's "Civil Engineering," it may be said that the average strength of Fujisan lies between that of rubble work and sandstone; Iwakisan, Nantaisan, and Alaid are like good rubble masonry, while the strength of the ill-fated Krakatāo is not much above that of ordinary brickwork.

8. *Theoretical Mountains.*—As it might be interesting to compare actual mountains with theoretical mountains constructed from the equation—

$$y = \frac{c}{2}\left(e^{\frac{x}{c}} - e^{-\frac{x}{c}}\right)$$

such mountains have been drawn, and are shown in Fig. 2. The values of c are given in the following table.

In drawing up the table, the instantaneous breaking strength of granite and its crumbling strength, which is the largest possible value for k, are taken as being equal. For sandstone the crumbling strength is assumed to be three-fourths of the breaking strength, while for rubble work and brickwork it has been taken as one-half.

Material	Instantaneous breaking strength in lbs. square feet	Crumbling strength or k in lbs.	Weight cubic foot lbs.	$c = \frac{2k}{\rho}$
Granite	1,584,000	1,580,000	170	18,500
Sandstone............	790,000	590,000	144	8,200
Rubble masonry ...	316,000	150,000	120	2,500
Brickwork	144,000	72,000	112	1,300

The diameter of the base of each of these mountains is 48,000 feet, and the height to which mountains of the following different materials could be built upon such a base without crushing would approximately be :—

Brickwork .... 4,600 feet	Sandstone...... 14,500 feet
Rubble masonry .. 7,300 ,,	Granite......... 20,000 ,,

9. *Causes Modifying Volcanic Forms.*—Causes modifying the natural curvature of a mountain are :—

(1) The tendency during the building up of the mountain of the larger particles to roll farther down the mountain than the smaller particles.

(2) The effects of atmospheric denudation, which carries materials from the top of the mountain down towards the base.

(3) The position of the crater, and the direction in which the materials are ejected.

(4) The existence of parasitic craters on the flanks of a mountain.

(5) The direction of the wind during an eruption.

(6) The sinking of a mountain in consequence of evisceration beneath its base.

(7) The expansions and contractions at the base of a mountain due to the acquisition or loss of heat before and after eruptions.

10. *Effect of Volcanic Eruptions on the People.*—The eruptions in Japan from time to time have exerted a very marked influence upon the minds of the Japanese people. Divine interference has been sought to prevent eruptions, priests have been ordered to pray, taxes have been repealed, charities have been instituted, special prayers against volcanic disturbances have been formulated, and have remained in use for the period of 100 years, while special days for the annual offering up of these prayers have been appointed. At the present day a form of worship to mountain deities is not uncommon.

SOLUTION[1]

Opening of the Discussion by Prof. Tilden

FOR want of time, the consideration of various phenomena connected with the subject was necessarily omitted. Thus no reference could be made to the various formulæ relating to expansion or density of solutions, nor to their optical properties, magnetic rotation, nor to the subject of electrolysis. In what follows, a review is presented of the principal phenomena observed in the act of solution of solids (especially metallic salts and other comparatively simple compounds) in liquids, and the chief properties of the resulting solutions, with the object of arriving (if possible) at some conclusion as to the physical explanation of the facts. The question must at once arise whether these phenomena are to be considered as chemical or mechanical, and all the theories which have been put forward to explain the nature of solution are roughly divisible into two classes, according as, on the one hand, they represent the process as a kind of chemical combination, or, on the other, explain the phenomena by reference to the mechanical intermixture of molecules, or by the influence of the rival attractions of cohesion in the solid and liquid, and of adhesion of the solid to the liquid. The former hypothesis seems to have been universally adopted by the older writers, such as Henry and Turner, and it seems pretty clear that Berthollet also regarded solution as an act of chemical combination. Among modern chemists, Prof. Josiah P. Cooke takes a similar view, but M. Berthelot is the most consistent and powerful supporter of the same hypothesis. In his "Mécanique Chimique," tome ii. p. 160, will be found a very clear and formal statement of the views upon this subject which, it is interesting to know, are retained by M. Berthelot without modification in any essential particular.

On the other hand, there are a number of writers who, whilst referring the phenomena of solution to a molecular attraction of some kind, do not attribute solubility to the formation of chemical compounds of definite composition. Graham distinctly ranges himself on this side. Brande also appears to have taken a similar view; Daniell, Miller, Nicol, and Dossios may be more or less ranked with them. A theory differing in some important respects from those of the above writers was briefly enunciated in a paper communicated to the Royal Society by Tilden and Shenstone in 1883. In discussing the connection between fusibility and solubility of salts, the authors point out that the facts tend to "support a kinetic theory of solution, based on the mechanical theory of heat. The solution of a solid in a liquid would accordingly be analogous to the sublimation of a solid into a gas, and proceeds from the intermixture of molecules detached from the solid with those of the surrounding liquid. Such a process is promoted by rise of temperature, partly because the molecules of the still solid substance make longer excursions from their normal centre when heated, partly because they are subjected to more violent encounter with the moving molecules of liquid." This theory, however, only relates to the initial stage of the process of solution, and does not sufficiently explain saturation nor the influence of dissolved substances upon vapour-pressure, specific heat, specific volume, &c. How far is it true that evolution of heat indicates chemical combination: does the evolution of heat which often takes place on dissolving a solid in water, or on adding more water to its solution, indicate the formation of hydrates, *i.e.* compounds of the dissolved body with water in definite proportions? Thomsen answers this question in the negative ("Thermochemische Untersuch.," Band iii. p. 20).

Take the case of sulphuric anhydride (SO_3). It is evident from the diagram exhibited that more than half the total evolution of heat occurs on addition of the first molecule of water to the solid substance; yet the succeeding molecules give quite an appreciable thermal change. At what point in such a curve should we be justified in setting up a distinction between the effect due to chemical combination and that due to other causes, such as the change of volume consequent on dilution or the possible loss of energy from the adjustment of the motion of the molecules of the constituents to the conditions requisite for the formation of a homogeneous liquid, or (though not in the present case) the decomposition of the compound by the water? In the act of solution of the solids, and especially of anhydrous salts in water, the volume of the solution is always less than the sum of the volumes of the solid and its solvent, with the exception of some ammonium salts in which expansion occurs. Similarly the addition of water to a solution is followed by contraction. This contraction may be due to mere mechanical fitting of the molecules of the one liquid into the interspaces between the molecules of the other (see Mendelejeff's abstract in *Journ. Chem. Soc.*, Feb. 1885, p. 114). This would probably not be attended by loss of energy. Or the contraction may arise from the readjustment of molecular motion already referred to.

If we know the coefficient of expansion of the liquid and its specific heat, we can calculate the amount of heat evolved for a given contraction. If this is done for sulphuric acid, and many other cases, it is found that, after accounting for the thermal change due to alteration of volume alone, there is a surplus of heat evolved which may really indicate some kind or some amount of chemical combination.

Thomsen has found that as a rule the heat of solution and of dilution are both either positive or negative. Of thirty-five salts examined, only four supply well-marked exceptions. However we may ultimately explain the anomaly exhibited by these salts, the fact remains that the heat evolved or absorbed during the admixture of any substance with water is in every case a continuous function of the quantity of water added. Similarly

[1] Report of a discussion at the Birmingham meeting of the British Association.

the contraction which ensues on diluting an aqueous solution proceeds continuously, and the molecular volume of a salt in solutions of different strengths is continuously greater the larger the amount of salt present. So that in none of these thermal or volumetric phenomena is any discontinuity observed, or any indication of the formation of compounds of definite composition, distinguishable by characteristic properties.

The question we are now considering, as to whether in a solution the solvent and the substance dissolved in it—or any portion thereof—exist independently of each other, is in some degree answered by the facts known as to the specific heats and vapour-pressures. For instance, when water is added to a solution of sodium nitrate, the molecular heat of the resulting liquid seems to show that all the water added is influenced at least until a very large quantity is present. In this case one molecule of sodium nitrate can affect the movements of a hundred molecules of water, and probably more. It is also well known that the vapour-pressures of water holding in solution almost any dissolved solid is less than the vapour-pressure of pure water, and that the boiling-point of a liquid is raised by the addition to it of any soluble non-volatile substance. This fact of reduction of pressure can only be explained upon the hypothesis that there is no free water present at all; that is, that there is no water present which is not more or less under the influence of the dissolved substance.

What becomes of water of crystallisation forms a part of the same question as to the relation of solvent to solvent. Observed facts lead us to conclude that white copper sulphate, blue anhydrous cobalt chloride—and, by analogy, other salts which are colourless—retain their hold upon water of crystallisation when they are dissolved in water. A very important observation has been made by Dr. Nicol which bears directly upon this question. In his study of the molecular volumes of salt solutions he finds that, when a salt containing water of crystallisation is dissolved, this water is indistinguishable by its volume from the rest of the water of the solution. In the report presented to the British Association last year, the following passage occurs: "These results point to the presence in solution of what may be termed the anhydrous salt in contradistinction to the view that a hydrate, definite or indefinite results from solution; or in other words, no part of the water in a solution is in a position relatively to the salt different from the remainder."

These two statements, however, are not strictly consequent upon each other. The view seems preferable that (save, perhaps, in excessively dilute solutions) the dissolved substance is attached in some mysterious way—it matters not whether it be supposed to be chemical or physical—to the *whole* of the water. We cannot otherwise get over the difficulty presented by the hydrated salts, which give coloured solutions, by the control of the vapour-pressure of the dissolved salt, and by the altered specific heat. With regard to water of crystallisation, E. Wiedemann has shown that hydrated salts in general expand enormously at the melting-point; and the observations of Thorpe and Watts on the specific volume of water of crystallisation in the sulphates of the so-called magnesium group show that, whilst the constitutional water occupies less space than the remaining molecules, each successive additional molecule occupies a gradually increasing volume. So that when a salt, with its water of crystallisation, passes into the liquid state (either by melting or by solution in water), it requires a very slight relaxation of the bonds which hold the water to the salt for it to acquire the full volume of liquid water, whilst the water of constitution is not so easily released. And this conclusion accords with Nicol's observations on the molecular volumes of the salts when in solution.

Now comes the question as to what determines the solubility of a substance. Why, for example, is magnesium sulphate very soluble in water, whilst barium sulphate is almost totally insoluble? With regard to salts the following propositions seem to be true:—(1) Nearly all salts which contain water of crystallisation are soluble in water, and for the most part are easily soluble; (2) insoluble salts are almost always destitute of water of crystallisation and rarely contain the elements of water; (3) in a series of salts containing nearly allied metals the solubility, and capacity for uniting with water of crystallisation generally, diminish as the atomic weight increases.

The fusibility of a substance has also much to do with its solubility. Neither fusibility alone nor chemical constitution alone seems to be sufficient to determine whether a solid shall be soluble or not. But it may be taken as a rule to which there are no exceptions that when there is a close connection in chemical constitution between a liquid and a solid, and the solid is at the same time easily fusible, it will also be easily soluble in that liquid.

Salts containing water of crystallisation may be considered as closely resembling water itself, and these are for the most part both easily fusible and easily soluble in water. But space is wanting for the discussion of the details of these matters, as well as of the relation of molecular volume to fusibility of solids.

The fascinating character of the phenomena of supersaturation has attracted a host of experimenters, but no definite explanation has been generally accepted. In the opinion of the speaker supersaturation is identical with superfusion. Supersaturated solution of, say, alum, thiosulphate of sodium melted in its water of crystallisation, and fused sulphur at 100°, exhibit phenomena of exactly the same kind.

Finally, we are led to the consideration of what is meant by chemical combination. From the phenomena under discussion, and others, the conclusion seems inevitable that chemical combination is not to be distinguished by any absolute criterion from mere physical or mechanical aggregation; and it will probably turn out ultimately that chemical combination differs from mechanical combination, called cohesion or adhesion, chiefly in the fact that the atoms or molecules of the bodies concerned come relatively closer together, and the consequent loss of energy is greater.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—Of the students in Natural Science entered at Cambridge this term no fewer than 116 have already announced their intention of studying medicine.

DUBLIN.—The Senate of the Royal University has conferred the degree of Doctor of Science *honoris causâ* upon James Bell, Ph.D., F.R.S., Principal of the Somerset House Laboratory.

SCIENTIFIC SERIALS

Revue d'Anthropologie, troisième série, tome 1, Paris, 1886.—On the Simian characters of the Naulette jaw, by M. Topinard. This celebrated find, which was discovered at the bottom of an obscure cavern 25 m. below the present level of the Lesse, near Dinant, in Belgium, is chiefly remarkable for its excessive prognathism, which is due alike to the great thickness of the horizontal branch of the jaw when compared with its height, and to the special obliquity of the axis of the alveolus of the second molar. In its relative proportions the Naulette jaw must be characterised not only as non-human, but as plus-Simian. A careful comparison of the Naulette jaw with the maxillary processes of the anthropoids, and of several of the lowest extant human races, has led M. Topinard to the conclusion that in the age of the mammoth, tichorine rhinoceros, and cave-bear, there had already appeared numerous mixed human types, to one of the lowest of which it may be presumed that the Naulette jaw belonged.—On the population of Bambouk, on the Niger, by Dr. Colin. An interesting paper on an extensive, but very imperfectly-known, region of Western Soudan, exclusively inhabited by a branch of the great Manding race, known as the Mali-nkès. The Bambouk territories, more than 600 kilometres in length, and from 80 to 150 in width, are divided into numerous little States, most of which enjoy a complete autonomy. Their want of consolidation, and the indifference of the people to all forms of religion, have made the Mali-nkès objects of contempt to their Mussulman black neighbours, but according to the narrations of the Griotes, or itinerant bards, who are to be met with in every part of Western Africa, they had at one time extended their dominion over all the tribes on the right banks of the Niger, and were preparing to invade Saigon when the advance of the French forced them to fall back within their original limits. For a time they submitted to the restrictions of Mohammedanism, but now they appear to have absolutely no religion. They prepare an intoxicating drink from honey, called "dolo," in which women as well as men indulge to excess. The men are indolent, hunting only to avert starvation, and working their extensive gold-mines imperfectly, and chiefly by the help of the women, to whom falls the chief share of providing for the wants of the community, but who, after marriage, enjoy great freedom, although the young girls are kept under strict supervision.—On the human bones found in France in caverns belonging to the Quaternary age, by M. Cartailhac. Of such finds, none can be referred to the early period of the Saint Acheul, or Chelles deposits, the oldest belonging apparently to the Mousterian age, while the most abundant human remains are found in the comparatively recent beds of Solutré and La Madelaine. The former of these are remarkable for the enormous number of horse-bones accumulated about the stone hearths and in the kitchen-middens of this station. According to Dr. Cartailhac, 40,000 skeletons might be reconstructed from these equine remains, which seem to have been exposed to the action of fire, the greater number of the bones having been broken for the extraction of the marrow, whence he assumes that the horse must have reached its maximum development and served in the place of all other game at the period of the Solutré deposits. The writer compares together the human and other remains found in various Mediterranean and inland caves, with the special object of ascertaining how far the condition and mode of deposition of the skeletons can throw light on the vexed question whether the great preponderance of fractured over whole bones in these primæval graves indicates the practice of cannibalism, or whether it may not be dependent on the observance of special modes of burial, involving the burning or dismemberment of the body after death.—The facial angle proposed by Cuvier and Geoffroy Saint-Hilaire for comparative anatomical determinations and for measuring facial differences in the living subject, by Dr. Collignon. The writer, who considers at length the merits of the various angles proposed by Camper and others, concludes by showing the superiority, for practical purposes, of adopting Cuvier's facial angle, measured by Topinard's goniometer for determining the median angle.

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, October 26.—M. Jurien de la Gravière, President, in the chair.—On the unequal flow of gases, by M. Haton de la Goupillière. In continuation of his recent communication on this subject the author here deals with the reverse problem of a receptacle originally filled with compressed air discharging itself freely into the atmosphere.—On the intensity of the magnetic field in dynamo-electric machines, by Marcel Deprez. Assuming that the most important element of a dynamo-electric machine, whether employed as a generator or receiver, is the magnetic field, the author deals with the influence of the deviation of the magnetic pieces, and shows that, contrary to the opinion of certain electricians, the intensity of the field decreases far less rapidly than the distance of the magnetic pieces increases. The influence of the dimensions perpendicular to the lines of force is also considered.—Researches on the decomposition of the bicarbonate of ammonia by water, and on the diffusion of its components through the atmosphere, by MM. Berthelot and André. From the experiments here described, the authors are led to the conclusion that it is the diffusion of the carbonic acid that determines the decomposition by water of the bicarbonate of ammonia, and consequently the transport of the ammonia itself. These results are of the greatest importance even for the purely physical study of the circulation of gases between the ground, the waters, and atmospheric air, apart altogether from the phenomena of vegetation.—Note accompanying the presentation of his work entitled "An Introduction to the Study of the Human Races," by M. de Quatrefages. This is the first volume of the "Bibliothèque d'Ethnologie," edited jointly by the author and M. Hamy. It contains a summary of the views expounded in greater or less detail in his other writings, while dealing more fully with a number of other matters, which he had hitherto merely indicated, or else entirely neglected for lack of the fresh data and discoveries which now enable him to discuss them seriously. One of the most important is the question of prehistoric man, and he now shows that even in Quaternary times the human race had already spread over the whole earth to the remotest extremities of the Old and New World. This ubiquity of Quaternary man already suggested the existence of the species in the previous epoch, and direct proofs of this fact have recently been multiplied to such an extent that the presence of man in Europe during Tertiary times may now be regarded as placed beyond reasonable doubt, although his presence in America is not yet established. The results yielded by palæontology, geology, and even history point to the extreme north of Asia as the cradle of the human race and the centre of dispersion, which had already begun in Tertiary times. Here also were differentiated the three fundamental types, to which all races may still be reduced, as well as the three linguistic types diffused throughout the globe. It is further shown that hypsistenocephaly is the main feature distinguishing the American from the European primitive race, and that the man of Canstadt, hitherto regarded as the oldest Quaternary type, in reality dates back to the Tertiary epoch.—Note on the meteorite which fell on January 27, 1886, at Nammianthul, in the Presidency of Madras, by M. Daubrée. This meteorite, a specimen of which has been received from Mr. Medlicott, of the Indian Geological Survey, presents the ordinary characters of the group of small sporadic asters.—Experiments on the transmission of force by means of a series of dynamo-electric machines coupled together, by M. Hippolyte Fontaine. These important experiments (carried out with seven Gramme machines, under the inspection of the Commissioners, MM. Bertrand, Becquerel, Cornu, Maurice Lévy, Marcel Deprez, and Mascart) show that it is possible to transmit an effective force of fifty horse-power through a resistance of 100 ohms at a loss of less than 50 per cent.—On algebraic surfaces capable of a double infinity of birational transformations, by M. E. Picard. In supplement to his previous communication on algebraic surfaces, the author here shows that, for all surfaces capable of a double infinity of birational transformation, the co-ordinates of any given point are expressed by the uniform (Abelian) functions of two parameters.—On the transformation of surfaces in themselves, by M. H. Poincaré. It is shown in connection with M. Picard's theorem that, in certain cases, the Abelian functions may degenerate into triply periodical, elliptical, or even rational functions.—Extension of Riemann-Roch's theorem to algebraic surfaces, by MM. Noether.—On the recomposition of white light by means of the colours of the spectrum, by M. Stroumbo. A process is described by means of which the recomposition of white light is effected, taking as the starting-point the very colours of the spectrum, and utilising, as in Newton's experiment with the disk, the persistence of the images on the retina.—Note on the principal showers of shooting-stars and the aurora borealis, by M. Ch. V. Zenger. A careful study of M. Rubenson's great Catalogue of the Auroras from 1800 to 1877 has unexpectedly revealed the fact that August 10 and November 14 show a great frequency of these lights, thus coinciding with the periods of the shooting-stars and suggesting a connection between these two orders of phenomena.—Influence of the amplitude of the lunar oscillation in declination on the shiftings of the northern trade-winds, by M. A. Poincaré. A study of the tables for 1880 83 shows certain relations between these phenomena, which, however, differ greatly according to the seasons.—On the phenomena associated with the heating and cooling of molten steel, by M. Osmond. It is shown that, as the quantity of carbon is increased, the temperature of transformation of the iron is lowered, and that of recalescence raised, so that both coincide in the hard steel.—Saturation of normal arsenic acid by the water of baryta, by Ch. Blarez.—On the function of the semicircular canals of the inner ear, by M. Yves Delage. The chief function of this apparatus, as already recognised by Goltz, Flourens, and others, is shown to be distinct from that of the auditory sense, and connected rather with the rotatory movements of the head, either alone or with the body.—On Syndesmis, a new type of Turbellariæ described by W. A. Sillimann, by M. Ph. François. This organism is shown to be, not an ectoparasite of the large green nematoid, as supposed by Sillimann, but a true endoparasite of *Strg. lividus*.—On two Synascidians new to the French sea-board (*Diazona hebridica*, Forbes and Goodsir, and *Distaplia rosea*, Della Valle), by M. A. Giard.—Organisation of *Lepidomenia hystrix*, a new type of Solenogaster, by MM. Marion and Kowalevsky.—On the Gephyrians belonging to the family of the Priapulidæ collected by the Cape Horn Mission, by M. Jules de Guerne. The discovery of these organisms is a remarkable instance of the presence in the southern seas of forms almost identical with those of the Arctic Ocean.—The simple epidermis of plants considered as a reservoir of water, by M. J. Vesque.—Remarks on *Poroxylon stephanense*, by MM. C. Eg. Bertrand and R. Renault.—On the taxonomic importance of the petiole, by M. Louis Petit.—On the reproductive organs of vegetable hybrids, by M. Léon Guignard.—On the relations of geodesy and geology: a reply to the observations of M. Faye, by M. A. de Lapparent.

BERLIN

Meteorological Society, October 5.—Dr. Brix, in the name of the Telegraph Administration, handed over to the Society a paper containing the results of observations respecting earth-currents instituted through the medium of German telegraph lines, and giving a brief history of these investigations.—Dr. Assmann spoke of the thunderstorms of the summer of 1886.

Physical Society, October 22.—Prof. von Helmholtz in the chair.—Prof. Börnstein communicated the results of his investigations into the thunderstorms of July 1884. The days from July 13 to 17 were very prolific in thunderstorms, and respecting them the speaker had collected and elaborated observations from more than 200 stations in Germany. For twenty-four separate thunderstorms, drawings were made of the "isobronts," isobars, and isothermals, from which it appeared that a fall in the barometer always preceded the outburst of the storm; that with the occurrence of the sinking of the barometer the atmospheric pressure rose very steeply and then relapsed gradually to its former level; and that the temperature, which was very high before the storm, declined rapidly with the outbreak of the storm. Local observations had formerly led to the same result. The "isobronts," or the lines uniting the places where the first peal of thunder was simultaneously heard, had in general a north-south direction. The "isobronts" made the passage from west to east with an average swiftness of from 38 to 39 kilometres an hour. The "isobronts" were attracted by the mountains, so that the part in whose west-east direction a mountain was situated approached it sooner, and, after the passage of the "isobront," delayed there longer than did the remaining part. Rivers retarded the progress of thunderstorms, and small thunderstorms often terminated at large rivers without crossing them. This relation of thunderstorms to mountains and rivers might be explained on the assumption that the storms were caused by ascending air-currents. When such an ascending air-current approached a mountain, then the mountain hindered the horizontal air from flowing in at the anterior side of the ascending current. The air flowing in at the posterior side, on the other hand, thereby obtained the preponderance, and urged the phenomenon with all the greater force to the mountain. The reverse occurred after the thunderstorm had surmounted the mountain. The horizontal currents in front then obtained the preponderance, and delayed the progress of the storm. The influence of the rivers found its explanation in the fact that the air above the water was considerably cooler than the air above the land, whereby a descending air-current was continuously maintained, operating in opposition to the ascending current of the thunderstorm, to the possible degree even of annulling it. The speaker had been able artificially to produce an imitation of all these processes by causing, in accordance with the directions of Dr. Vettin, visible currents to ascend in a glass box filled with tobacco smoke, by means of local depressions of temperature, by setting these currents in constant motion, and making them strike against obstructions (corresponding with the mountains), as also on descending currents which were likewise artificially created. In the discussion which followed the above address, Dr. Vettin laid stress on the fact that precisely at the moment when the barometer mounted steeply from its lowest position, the thunder followed the lightning most rapidly, and discussed how, in accordance with his conception of the nature of thunderstorms, by the curving round of the ascending air-current, a whirling movement round a horizontal axis came into shape, whereby, as determined by its situation and its extent, were produced thunderstorms, sleet, and hail.—Prof. von Helmholtz described the formation of a thunderstorm observed by him in Rigi-Kaltbad. From a free point of prospect, allowing a survey of the plain as far as the Jura, he observed how the lower warm and moist layer of air was distinguished by a sharp horizontal boundary of somewhat long strips of cloud from the upper dry and cooler air. The cloud-masses resembling the stripe-shaped cirri diffused themselves and formed a coherent level boundary-layer between the two air-masses. He next noticed, at different spots, balls of cloud arise above the boundary-layer, evidently as the effects of ascending air-currents. The different cloud-heaps then rose higher and grew into larger cloud-masses within which different electric sparks leapt from one spot to another. It was only subsequently that he saw the lightning fly downward to the earth. At last a heavy rain rendered the lower air-mass, bounded by the horizontal cloud-basis occupying a position nearly at a level with the height of the stand-point, which had hitherto been clear, opaque. The phenomenon had developed itself under weather in which the wind was at rest, and could be followed very precisely into its details.—Prof. Schwalbe reported on an investigation of Herr Meissner, who, in the Strasburg Laboratory, had determined the warmth effect on the wetting of powdery bodies. In the way of powder were used amorphous silicic acid, glass, emery, carbon; as fluids, distilled water, benzol, and amyl alcohol. In all cases an increase of temperature was observed.

LETTERS AND JOURNAL OF W. STANLEY JEVONS

Letters and Journal of W. Stanley Jevons. Edited by His Wife. (London: Macmillan and Co., 1886.)

A STRIKING but sad book is this autobiography; for though "written to give the best idea of the character of the man in the various relations of life more than to recount scientific work," it is practically an autobiography: there is scarcely a critical remark upon his thoughts or conduct in it.

The family for many generations had been settled in Staffordshire. The grandfather came to Liverpool, and commenced business as an iron-merchant there, and his son Thomas, a man of ability in many ways, joined him in it. This was the father of William Stanley Jevons, who had, moreover, the almost invariable precedent of a clever man (*pace* Mr. F. Galton), viz. a clever mother, whom, however, he had the misfortune to lose at ten years old. She was the daughter of William Roscoe, author of the "Life of Lorenzo de Medici" and "Leo the Tenth." Another misfortune, from which, however, he learnt the value of money in a practical sense, befell him at the age of thirteen, when the firm of Jevons and Sons failed; and his grandfather, who died in 1882 at the advanced age of ninety-one, came to live with them.

A characteristic very marked, and to a marvellous extent affecting his whole subsequent life, was a bashfulness or "natural timidity of character which," his father wrote him, "is the worst, or perhaps I may say the only, weakness you have." This led to self-depreciation, and at school the French master complained that he was far too quiet and made no noise, and did not read above his breath. Shrinking from his companions and their fun, however, he early acquired the habit of directing his attention and mental powers at his will, and nothing tried his naturally passionate temper more than to be compelled to leave the pursuit of the moment while still engrossed in it. Reports of him as a scholar naturally kept continually improving, and, though laboriousness is throughout his characteristic, his sister writes in her diary that she saw in Stanley at the age of fourteen the dawnings of a great mind.

Botany and chemistry, in both of which he subsequently took honours, were the two sciences which attracted him first. The former was begun under the loving eye of his mother: the latter was the first that he took up at University College School, and "followed fiercer and fiercer till he gained the University gold medal."

He had decided at seventeen to go into a chemical manufactory at Liverpool, in order to remain near home; but before he had ended his last term of study at the University his wishes and plans were all upset by Profs. Williamson and Graham recommending him for the appointment of Assayer to the new Mint in Australia. He shrank from it as being too heavy a post for a youth of eighteen, and as going terribly against his wish to settle at home. But an income of 675*l.* a year was too good an offer to be refused. On June 29, 1854, not yet nineteen years old, he set sail for Sydney.

While at Sydney he attacked the Australian meteorology, and published his observations; more, as he explains, to show what phenomena had to be solved and what interesting connections of cause and effect might be suggested. Geology also, which he had commenced shortly before he left England, he there followed up. There he first suggested a collection of newspapers from all parts of the world as a curious exhibition; there also he heard of the death, after seven years of reviving prosperity in trade, of his father in November 1855. Though doing so well financially, he still cherished the feeling that he was losing time which he might put to better advantage. After four years he resigned his post, and on his return, *viâ* Callao, Panama, St. Thomas, Havanna, and several cities of the United States, he made his way up country past Minneapolis, to visit a brother who had gone out to settle there. Returning thence by way of Niagara and Montreal to New York, he landed at Liverpool, but soon went on to London and re-entered the University. He joined several senior classes in company with his younger brother, whose education he was then paying for. He had decided thenceforth to follow up political economy and mental philosophy.

His "Theory of Political Economy" was read as a paper but not "approved" by the British Association at Cambridge in 1862. It was published in 1871, and reached a second edition in 1879. Though it attracted the attention of some eminent foreigners, it was coldly received in England—the free use of mathematical symbols placing it above the heads of those practically engaged in commercial pursuits. In 1875, at the British Association meeting at Bristol, he read another well-known paper on the connection between sunspots and the price of corn—bad crops of the latter, we need hardly add, being followed by a high price and bad trade—and though he spoke at first very doubtfully of his theory, yet up to the time of his death, in 1882, he believed that a great revival of trade would take place almost immediately, to be followed by seven years of unprecedented prosperity, and he had speculated accordingly. Gold, however, alas, seems a more important factor than sunspots.

A more famous paper still was his "Coal Question," published in 1865. It was a question in which the whole nation took an interest, and it supplied a text for one of Mr. Gladstone's economical budgets. Accordingly it was discussed in every paper, political, economical, or social, and is perhaps better known now than any of his other writings.

His earlier writings had brought him in very little, and in 1863 he had accepted the not very lucrative post of tutor at Queen's College, Manchester. In 1866 he was appointed Professor of Logic and Mental and Moral Philosophy, and Cobden Professor of Political Economy, at 300*l.* a year. A thorough teacher, he was much liked by his pupils, never tiring of making them understand, and watching their careers in after life.

In December 1867 he married the daughter of Mr. J. E. Taylor, founder and proprietor of the *Manchester Guardian.* To her we are indebted for this well-arranged selection of letters.

In 1864 he published his first work on "Pure Logic," chiefly founded upon Prof. Boole's system. In 1865 he invented a logical machine or abacus which he describes as working in a few moments any logical problems involving no more than four distinct terms or things. It was like a small piano, three feet high, with twenty-one keys. A second book upon logic was published in 1869, just after this had been made to work correctly, entitled "The Substitution of Similars," containing a sketch of the fundamental doctrine of his great work, "The Principles of Science," which was not published in full till 1874, but reached a second edition in one volume in 1877.

In 1870 his "Elementary Lessons in Logic" appeared in Macmillan's series of science class-books, followed in 1876 by the "Primer of Logic," one of the same publishers' more elementary series; and in 1880 "Studies in Deductive Logic" for students desiring a more thorough course of logical training.

In 1868 he had prepared three articles attacking J. S. Mill's system of logic. They were declined at first, but three years afterwards, soon after the death of Mr. Mill, they were accepted by the *Contemporary Review*. It is curious to see two such mighty champions of such a learned science referring their differences to an uneducated public and to their instinctive logic!

Though sorry on many accounts to leave Manchester, his heart had never left London and its University, to which he returned in 1876 as Professor of Political Economy. In that year he boldly read a paper laying it down that the United Kingdom Alliance was the worst existing obstacle to temperance reform in the kingdom—driving the enemy to a man into fierce opposition.

His first illness through over-work had occurred in 1869, and from that time his letters in large proportion are from various places — Norway was his favourite resort—to which he had been driven to regain strength. Trip after trip was taken, but with no permanent effect. As soon as he returned he again overwhelmed himself with work, involving too great tension of the brain. The labour especially of taking his class when out of sorts was a "painful" labour to him. To relieve himself from this he resigned his Professorship in 1880, and in 1882, after two years more of work at home, but still at high pressure, a plunge into the sea was too sudden a chill for his enfeebled frame, and insensibility and death were the sad result, at the prime age of forty-six.

One cannot help sorrowfully noting how his childish bashfulness was the cause of his early death. It led to unsociability and abstinence from recreation. Instead of rejoicing in his strength, he shunned his companions, and persuaded himself, moreover, that it was his duty to do so, though he bitterly regrets it afterwards, one result being an inability to speak in public and communicate his ideas as he would wish. The ardent cultivation of his many talents, again, increased a feeling of superiority, yet often left him low-spirited. In some it might have brought carelessness and improvidence, but in Jevons it was attended by a feeling of responsibility almost religious. At twenty-three he threw up his easy and lucrative post at the Sydney Mint in obedience to this feeling, and, later on, he resigned one laborious duty only to buckle to another, and under such labour his life was quenched.

GENERAL PATHOLOGY

An Introduction to General Pathology. By J. B. Sutton, F.R.C.S. (London: J. and A. Churchill, 1886.)

UNTIL recently, pathologists have confined their attention to studying the processes of disease in human beings, and but little effort has been made to take advantage of the vast field of material presented by the animals which die in the Gardens of the Zoological Society. Since 1878 the author has systematically examined the bodies of 12,000 animals and of over 800 still-born and immature fœtuses; and from this vast stock of material he has, for the purposes of the present work, selected, from all parts of the animal kingdom, striking examples which illustrate the main pathological and physiological processes of life. The same principles govern both, and processes which in one group of animals are the cause of disease, in another, owing to anatomical differences, habits of life, and surroundings, have no such influence. Moreover, pathological defects are frequently inherited, and become looked upon as racial peculiarities. Thus the horns of the Ungulata, the curved canines of the Babiroussa, the atrophied right ovary and right carotid artery in many birds, the large third with the small second and fourth metarcarpals of the horse, are now persistent, but were probably originally accidental and pathological.

The degree of development of the muscular tissue of the gizzard of a bird is dependent upon the nature of its food. The herring-gull of the Shetland Islands changes its food twice every year—in the summer living on grain, when its gizzard is of the granivorous type, and in the winter on fish, when the gizzard reverts to the carnivorous condition. The same variations have been artificially produced by varying the food of sea-gulls, pigeons, ravens, and owls. While excessive function is the great cause of hypertrophy of organs, deficient usage is the determining factor in the abnormal overgrowths of hair, nails, beaks, and teeth. Rodents in captivity frequently require their teeth to be artificially shortened in order to avert the fatal effects of excessive overgrowth.

Monkeys, when in confinement, frequently die with symptoms of more or less complete paraplegia, which has recently been shown to be due to an overgrowth (frequently rickety) of the vertebræ near the intervertebral lamellæ. This gradual compression of the cord also occurs in tigers, lambs, bears, and others. These facts observed in animals throw light upon the agonising pains of mollities ostium, which are doubtless in like manner due to compression of the cord and nerves, which is permitted by the softening of the bones which the disease causes.

Metschnikoff's definition that inflammation is a struggle between irritant bodies and white blood-corpuscles is adopted. Illustrations are given showing the white corpuscles surrounding and digesting micro-organisms and other foreign bodies, or dying in the attempt to do so. When the tails and gills of larval batrachians are being absorbed, numerous amœboid cells can be seen containing fragments of nerve-fibres and muscle.

Our present knowledge of the nervous system quite fails to offer any explanation of the experiment which the author performed by transposing the median and ulnar nerves in a cat. The two nerves were divided about the middle, and the distal end of the median was united to the proximal end of the ulnar, and *vice versâ*. Union occurred: sensation and motion returned in six weeks. The cat regained complete use of the limb, and did not appear to suffer any inconvenience. It would be of great interest to repeat the experiment by attaching the proximal end of the median to the distal end of the ulnar, but to prevent the other ends from uniting. Would the result be an unimpaired function of the median nerve, transmitted from the portions of the brain and cord formerly associated with the function of the ulnar?

The classification of the cysts and neoplasms of the animal kingdom are illustrated by many typical examples. The teratomata are fully discussed, and it is shown that they almost invariably occur only in spots where the epi-, meso-, and hypo-blastic layers have been temporarily but directly in continuity with each other. Thus præsacral tumours are associated with the obsolete neurenteric canal; pituitary tumours with the canalis craniopharyngeus (a canal through the floor of the basisphenoid), lingual dermoid cysts with the ductus thyreoglossus (a canal running from the basihyoid to the foramen cæcum of the tongue), and ovarian dermoid cysts with the obsolete Müllerian and Wolffian ducts. The predisposition of obsolete ducts to disease has for some time been recognised, but the close relationships of teratomata to such ducts is a more recent piece of work.

The novel illustrations of the leading pathological processes make the work one of extreme interest, and we heartily congratulate the author on the good use to which he has turned his exceptional opportunities.

PLANE GEOMETRY

The Elements of Plane Geometry. Part II. (corresponding to Euclid, Books III., IV., V., VI.). (London: Swan Sonnenschein, 1886.)

THIS book contains a revised edition of Books III., IV., V., of the "Syllabus of Plane Geometry" drawn up by the Association for the Improvement of Geometrical Teaching, with demonstrations of the propositions, and an excellent, though limited, collection of suitable exercises. If nothing else than these two parts had been the outcome of the movement first set on foot in our columns, the Association would have amply justified its formation. Much difference of opinion has prevailed as to the desirability or expediency of the Association producing such a work as this. The late Mr. Merrifield for some years strenuously opposed any such proceeding, but at the annual meeting of 1881 he expressed himself as "now satisfied from the experience which he had had in dealing with the examining bodies that they would not get their work really adopted by the public until they had a text-book. Everywhere he was met with the impossibility of wading through a dry Syllabus. Nobody who was not thoroughly versed in mathematics could judge whether there was any real possibility of teaching from the Syllabus at all." Circumstances appear to have compelled the Association at last to take the field with demonstrations put forward by a selected committee of its members: a principal reason being that the Association was bound to help teachers. The plan of teaching the Syllabus without giving written proofs was found to succeed so long as the teaching was confined to the earlier parts of the subject, but when the later books were reached it was found necessary to give formal written proofs for subsequent reference (Report, 1881, p. 30).

Some teachers who wish for the more copious introduction of modern ideas and methods into the very elements may not consider the work of the Association as satisfactory as could be wished, and may think there is very little of the influence of the aforesaid modern ideas in the Syllabus, yet even such admit, and express satisfaction in making the admission, that "the use of the Syllabus has spread pretty widely, and it is to be hoped that it will continue to do so" (Prof. Henrici, British Association address, NATURE, vol. xxviii. p. 500). It is to be borne in mind that the Professor hardly gave the Syllabus a fair trial, though he says that when it appeared "I resolved to give it a thorough trial, and took the best means in my power to form an opinion on its merits by introducing it into one of my classes. The fact that it did not quite satisfy me, and that I gave up its use again, does not of course prove that it fails also for use in schools, for which it was originally intended."

These students had, we assume, to take down in writing the Professor's proofs, and it is not as agreeable work to "grind up" manuscript as it is to read a printed page; then there would be by-gone remains of the old text-book haunting the students' brains, want of familiarity with the Syllabus possibly on the teacher's part, and finally shortness of time over which the trial extended. At this point we may cite some remarks by the late Dr. Todhunter, which make as much for Syllabus upholders as for Euclidians. "It will be hard to secure that pupils shall be selected of equal power, and be trained with equal assiduity; and then if our teacher is to try various methods he is liable, since he knows that a controversy is now existing as to the result, to deviate from impartiality in his treatment of the rival methods. Moreover, there may naturally arise some disagreement as to the means to be used for testing the value of the results, and as to the accurate application of the principle which may be finally adopted for this end" ("Conflict of Studies," &c., p. 156). A fair trial would be to take two classes of students of as nearly as possible equal mental calibre, and with equal want of acquaintance with geometry, and to take each through the respective courses for the same time, and to take care that each teacher should be equally skilled and acquainted with his author and equally enthusiastic, for, as our essayist just cited writes, "if the teacher is only languid without being positively hostile, his real sentiments are soon discovered: hypocrisy has but a slender chance of deceiving school-boys" (p. 164). But such a fancy is Utopian; the hope of the Association at first lies in such far-away parts as the Cape and India, where its work is being taken up by enthusiastic and able teachers.

We have read the proofs, and believe them to be thoroughly accurate; there is also a careful avoidance of all looseness of language. Dr. Todhunter's "deliberate judgment" was that "our ordinary students would suffer very considerably if instead of the well-reasoned system of Euclid any of the more popular but less rigid manuals were allowed to be taken as a substitute" (p. 168). So fearful was he of looseness or slipshoddiness that he more than once returns to this matter, and upon this very point of an Association text-book writes as follows:—"There are various considerations which seem to me to indicate that if a change be made it will not be in the direction of *greater rigour*" (p. 172). He owns himself once to have been in favour of *hypothetical* constructions, but that he had subsequently seen reason to alter his opinions: in many places in his essay he shows that he has not renounced *hypothetical* statements. His idea of an Associationist seems to have been that he is a being who tries to evade the difficulty of passing a pupil in geometry by asking for a less stringent text-book than that of Euclid.

It is vain to wish for the verdict of such able critics as De Morgan and Todhunter on the work before us, but we feel sure that the former would not have written concerning it "Non est geometria," nor the latter have found it wanting in Euclidian rigour.

As to this matter of a different order from Euclid's sequence we cite with cordial approval the following remarks of a writer in our columns (vol. xxxiv. p. 50):—"We believe that those who have most carefully considered the question of a rival order of sequence of geometrical propositions would agree that the best order in a logical arrangement does not seriously *conflict* with Euclid's order, except by simplifying it. Rather, by bringing the proofs of each proposition nearer to the fundamental axioms and definitions than Euclid does, it renders less assumption of previous propositions necessary for the proof of any given proposition. It stretches the chain of argument straight instead of carrying it round one or many unnecessary pegs."

The influence which the Syllabus has had upon modern editions of Euclid is patent to any reader of the works in question. And now, little book, that the Association has at the end of days sent forth on to (it may be) tempestuous seas, we wish thee *bon voyage!*

OUR BOOK SHELF

American Journal of Mathematics. Vol. viii. No. 4. (Baltimore, August 1886.)

THE number opens with a memoir, by M. Poincaré, "Sur les Fonctions Abéliennes." The author gives here a *résumé*, with additional details, of a demonstration and generalisation of two of Weierstrass's theorems, which he had previously published in the *Proceedings* of the Mathematical Society of France (tome xii. p. 124). He then extends a theorem of Abel's from plane curves to surfaces, and refers, for fuller details, to a crowned memoir of M. Halphen's, "Sur les Courbes gauches algébriques." He next discusses some properties of "fonctions intermédiaires," using the term in the sense given by MM. Briot and Bouquet. This memoir occupies fifty-four pages. The second paper, on "A Generalised Theory of the Combination of Observations so as to obtain the best Result" (24 pp.), is by the editor, Prof. Newcomb. A very valuable article, with important practical applications. The final article (22 pp.), "On Symbolic Finite Solutions and Solutions of Definite Integrals of the Equation—

$$\frac{d^n y}{dx} = x^m y,"$$

is by Mr. J. C. Fields. It discusses finite solutions analogous to the symbolic solutions of Riccati's equation.

A Sequel to the First Six Books of the Elements of Euclid; containing an Easy Introduction to Modern Geometry (with numerous Examples). By John Casey, LL.D., F.R.S. (Dublin: Hodges, 1886.)

THIS is the fourth edition of a book which has been received with warm approval by English and Continental geometers. The first eight sections present no notable changes from the corresponding sections in the last edition. In our previous notice (NATURE, vol. xxix. p. 571) we remarked that the author was "not so well up in the literature of the modern circles as he might be." This reproach is quite removed in the present edition. Indeed in this direction the author has himself now done excellent yeoman's service. The "supplementary chapter" of fifty-eight pages gives an admirable account of this modern branch in six sections. The first section states and illustrates the theory of isogonal and isotomic points, and of anti-parallel and symmedian lines. The second discusses "two figures directly similar" in homothetic figures. The third section is headed "Lemoine's and Tucker's circles." The fourth discusses the "general theory of a system of three similar figures." The fifth gives "special applications of the theory of figures directly similar," more particularly with reference to Brocard's circle and triangles. In the sixth section on the "theory of harmonic polygons," the author, starting from Mr. Tucker's extension of the Brocard properties to the harmonic quadrilateral, and Prof. Neuberg's continuation of the same, gives his own beautiful generalisations to the harmonic hexagon and other allied polygons. This latter extension has been made the subject of a communication by MM. Tarry and Neuberg to the French Association meeting at Nancy in August of the present year. The paper, which is not expected to be published until April 1887, contains a complete generalisation of points of Lemoine and Brocard, and the modern circles cited above for polygons and polyhedra.

The success of the "Sequel" is due to the fact that the author and the subject are exactly suited to each other: the union is a most harmonious one, and the result is a work indispensable to all lovers of geometry.

Geometrical Drawing for Army Candidates. By H. T. Lilley, M.A. Pp. x., 54. (London: Cassell and Co., 1886.)

IN a short introduction to this little work the author gives some useful advice to those beginning practical geometry, and rightly lays stress on the proper method of handling instruments, and on a good style of working.

The book contains altogether 300 problems in plane constructive geometry; they are nearly all straightforward and easy, but 180 of them are specially indicated as forming, according to the author's experience, a suitable first course for the majority of students.

The problems are conveniently grouped together, and hints are given in aid of the solution of typical ones, and of those presenting extra difficulty. Beginning with the construction of scales, we have the usual series on polygons, proportionals, equivalent areas, and, in conclusion, several cases of circles touching other circles or given lines.

As a book of examples this collection seems likely to prove useful in class-teaching. But in order to insure sound instruction, much that is not contained herein will have to be provided for the student. Thus in the notes to the problems before us no reasons are given or indicated for the various steps in the constructions, and there is no distinction drawn between those methods of construction which are exact, and those which do not admit of proof.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Enormous Loss from Ox-Warble

I HAVE read Mr. John Walker's remarks on "warbles." This is one of the many important subjects to which Miss Eleanor Ormerod has lately drawn attention. I can readily believe that there is a loss of two to three millions to the country through the ravages of this fly, but such statements, it must be remembered, should be qualified by the thought that it might cost two or three millions to protect all the cattle of this country against such attacks. The labour would be great, the vigilance would entail higher-classed stock-men, in almost all cases with higher wages, for you cannot get our labourers, dairy-men, and bailiffs even, to attend to such matters without great difficulty. The loss does not, I think, fall upon farmers, unless it is from the irritation to the cattle when they hear the buzz of the fly meditating her attack.

As to the damage to the hide, I never, in my experience, heard a butcher or dealer make warbles in the hide a pretext for offering one shilling less for a bullock. They take no notice of them at all; and, if the maggots injure the hide, this is a matter for fell-mongers and tanners, rather than for farmers. This is one of the cries emanating from the scientific friends of agriculture which it is well to listen to. It will probably gain the ear of only a select circle of agriculturists, because, to use a very homely phrase, "the game is scarcely worth the candle." Animals pass through the market too rapidly, and the prices asked and given are so approximate only to the absolute value, that a few warbles in the skin do not in the least influence the selling price. Still, anything which can be shown to influence the comfort of live stock or the value of their products must be considered as worth attention.

JOHN WRIGHTSON

College of Agriculture, Downton, Salisbury, October 31

"Lung Sick"

MR. H. RIDER HAGGARD, in his excellent novel, "King Solomon's Mines," has the following passage. He is speaking of Zulu oxen, and says:—

"As for 'lung sick,' which is a dreadful form of pneumonia very prevalent in this country, they had all been inoculated against it. This is done by cutting a slit in the tail of an ox, and binding in a piece of the diseased lung of an animal which has died of the sickness. The result is that the ox sickens, takes the disease in a mild form, which causes its tail to drop off, as a rule about a foot from the root, and becomes proof against future attacks."

Presumably this account is *bonâ fide*. It will be gratifying to me, then, if any of your correspondents will kindly explain how it is that the virus, which has not been weakened by cultivation, produces the disease in a mild rather than in a virulent form.

E. J. DUNGATE

6, Marchmont Road, Edinburgh, November 1

The Beetle in Motion

WITH reference to Prof. Lloyd Morgan's letter in last week's NATURE (p. 7), the following passage, which occurs in an interesting chapter on "Motions of Insects" in Kirby and Spence's "Entomology," may be quoted:—

"In walking and running, the hexapods, like the larvæ that have perfect legs, move the anterior and posterior leg of one side and the intermediate of the other alternately."

This passage is in complete accord with the observations of your correspondent. C. J. G.

November 9

Meteors

YESTERDAY (November 2), about 8.8 p.m., I chanced to see here a meteor that, I think, deserves record, especially if my report of its position in the sky can be compared with that of some one who observed it at another place.

Returning from Oxford, I was about half a mile east of Combe Church, on the lofty plat that is the remnant of Combe Common. "Stepping westward," I was startled by a sudden splendour, flooding with light the moonlit heaven. This splendour was above me and before me; it was a little on my left. A large meteor was rapidly descending, at an angle of 60° or 70°. Not much east of it shone the half-orbed moon; but little west of it stretched the eastern branch of the Milky Way's western termination. When it had traversed about three-fourths of the distance between its apparent starting-point and the undulating ground beneath, it swelled out for a moment grandly, and, before it burst, displayed a globe at least as big as the sun, and of about the same hue, though not of dazzling lustre. After it had vanished, its track was marked for a second or two by a brilliant trail, which, in the light of the neighbouring moon, sparkled with all the tints of the rainbow, and resembled a gorgeous shower of precious stones.

JOHN HOSKYNS-ABRAHALL

Combe Vicarage, near Woodstock, November 3

I HAVE read Mr. Murphy's letter (NATURE, November 4, p. 8). At the same time as Mr. Murphy saw a large meteor (October 31, 8.25 p.m.) I also saw an immense one coming from the same portion of the sky, and travelling west. It disappeared behind a cloud. There was a loud rushing noise.

INFLUENCE OF WIND ON BAROMETRIC READINGS

I AM glad to see (NATURE, vol. xxxiv. p. 461) that the Scottish Meteorological Society recognises the importance of the effect of wind upon the barometer. I assume that the gradient, the density, and all other sources of error had been fully corrected for before concluding the existence of the large effect attributed to the wind on Ben Nevis.

There certainly is a purely local and dynamic effect of the wind on the barometer due to the exposure, and for which there must be found some method of correction or elimination before we can proceed much farther in barometry: this effect has been independently reasoned out by G. K. Gilbert ("A New Method, &c.," 1883), and has been discussed by Prof. H. A. Hazen (*Annual Report*, C.S.O., 1882, p. 897), and by Mr. Clayton and others in recent numbers of *Science*, but its existence was long since demonstrated by Sir Henry James (*Transactions* Roy. Soc. Edinburgh, vol. xx., 1853), whose memoir seems to have been quite lost sight of by meteorologists.

The suction of wind on tubes, cowls, and chimneys was investigated by Ewbank (*Journal* of the Franklin Institute, 1842), Wyman (*Proceedings* of the American Academy, Boston, 1848), Fletcher (*B.A.S. Reports*, 1867 and 1869), Magius (Copenhagen, 1875?), Holten (Copenhagen, *Oversigt Vidensk-Selskabs*, 1877), and was used by Hagemann as the basis of his anemometer; it was Hagemann's memoir (Copenhagen, 1876, translation will appear in *Van Nostrand's Magazine*, Dec. 1886) that suggested a method of determining and correcting for the amount of this important effect, whose existence had long been known to me. This method is sketched out in the *Annual Report* of the Chief Signal Officer, U.S.A., 1882, p. 99, where I state that a close determination simultaneously of both dynamic wind-pressure and static air-pressure is probably attainable by exposing above the roof, side by side, a Pitot tube facing toward the wind and a vertical tube over which the wind blows. Close the lower ends of these tubes and place within each an aneroid barometer, and the latter will record respectively the static pressure plus the effect of the wind-velocity and the static pressure minus the wind's effect. A stop-cock, cutting off at will communication between the aneroids and the exposed mouths of the tubes, allows one to catch the influence of any gust and read the pressure at leisure.

The theoretical problem of the precise mechanical action of these tubes, especially that which Hagemann calls a Magius tube, *i.e.* one across which the wind blows at right angles, will, I hope, prove attractive to the mathematical physicists of England. Some interesting experimental work by Robinson will be found in *Van Nostrand's Magazine*, vol. xviii., 1878, p. 255, and xxxv., 1886, p. 89. A small closed room with only a chimney flue opened, such as usually obtains at the mountain stations of meteorologists, is virtually a Magius tube, and the barometer within must, under favourable conditions, show a depression depending on the so-called suction or draft up chimney. The direction of the wind combines with the structure of the building and the aspect of the various doors and windows to modify the influence of the force of the wind; the sluggishness due to the close cisterns, and the pumping due to the inertia of the liquid of ordinary mercurial barometers, further complicate the phenomena of suction during gusty winds, so that a simple general rule for correcting the observed barometric readings becomes impracticable, but the use of aneroids within closed Pitot or other tubes, with air-tight stop-cocks as above, simplifies the wind's action, and allows of its measurement at definite moments.

The distribution of pressure over the face of a large building fronting the wind, and in some part of which is the window of the room containing the barometer, is approximately known from Curtis's and Burton's measurements for a thin flat plate.

The location of each station with respect to mountains or other orographic features has also an influence on the pressure, which will still remain to be investigated; thus, on the leeward side there is a diminution, and on the windward side an increase of pressure, but this may be generally inappreciable.

It may also be mentioned in this connection that in delicate barometric measurements, such as those made by the International Bureau of Weights and Measures, it is important to prevent even the slightest currents from blowing across the open end of the siphon tube.

The suction effect of wind blowing over chimneys surmounted by cowls of different shapes was under investigation from 1878 to 1881 by a special committee of the Sanitary Institute, but, so far as I can learn, their experiments were never completed. Lord Rayleigh also read a short paper on the same subject at the meeting of the British Association in 1882, but as I do not know of its publication, I take this opportunity to express the hope that he will give meteorologists both a theoretical and experimental exposition of the action of the Pitot, the Magius, and the reversed Pitot tubes, and a suggestion as to the best method of determining, by means of stationary apparatus, the static pressure within a mass of moving air. CLEVELAND ABBE

Washington, October 23

M. PASTEUR'S TREATMENT OF RABIES

AT the meeting of the Paris Academy of Sciences on November 2, M. Pasteur submitted a further communication on the results hitherto obtained from his method of treating hydrophobia by inoculation, which has now been in operation for a twelvemonth. The paper is divided into three parts, the first giving the statistical details brought down to the present date, the second describing certain modifications in his method as originally applied, the third giving the results of fresh experiments on animals. Up to October 31 as many as 2496 persons were inoculated at his Paris establishment, and at first the treatment was uniform for all alike, whatever their age, sex, or other varying conditions. Of the total number 1726 were from France and Algeria, 191 from Russia, 165 from Italy, 107 from Spain, 80 from England, 57 from Belgium, 52 from Austria, 22 from Roumania, 18 from the United States, 14 from Holland, the rest from various other parts of Europe, besides 3 from Brazil and 2 from British India. Of 1700 French patients, apart from 2 who arrived too late, 10 only succumbed, whereas of the small minority not treated at the laboratory as many as 17 died in the same period in the rest of France, while for the last five years the average yearly mortality from hydrophobia was 11 in the Paris hospitals alone. Last year it rose to 21, but since November 1885, when the new system was introduced, 2 only died, and these had not been inoculated, besides a third who had been imperfectly treated. Most of those who perished were children bitten in the face and subjected to the simple treatment, which experience now shows to be insufficient in such cases.

A first lesson on the necessity of stronger doses was taught by the 19 Russians bitten by a mad wolf, one of whom died while under treatment, and two others shortly after. In consequence of these deaths the 16 survivors were subjected to a second and third treatment with the strongest and freshest virus from the spine of the rabbit of 4, 3, and 2 days' standing, whereas, for the milder treatment, virus from 14 to 5 days' old had alone been used. To these repeated treatments should most probably be attributed the recovery of these Russians, who are reported to be all still in excellent health.

Encouraged by these results and by the fresh experiments described further on, M. Pasteur modified his treatment, making it at once more rapid and more active for all cases, and even still more energetic for bites on the face, or for deep and numerous lacerations of exposed parts of the body. In such cases the inoculations are now hastened, in order to arrive more promptly at the freshest virus. Thus, on the first day, virus of 12, 10, and 8 days will be used at 11, 4, and 9 o'clock; on the second day that of 6, 4, and 2 days, at the same hours; on the third, virus 1 day old. Then the treatment is repeated: the fourth day with virus 8, 6, and 4 days old; the fifth with that of 3 and 2 days; the sixth with that of 1 day; the seventh with virus of 4 days; the eighth with that of 3; the ninth that of 2; the tenth with that of 1 day.

If the bites are not healed, or the patients arrive somewhat late, the same treatment may be renewed at intervals of two or a few days for four or five weeks, which are the critical periods for children bitten in the face. This system of vaccination has been in operation for the last two months, hitherto with excellent results, as shown by comparing the case of the six children who perished under the mild treatment, with that of ten others also seriously bitten last August, and subjected to the more energetic treatment, and all of whom were doing well on the first of this month. This new system requiring an increase of the staff, M. Pasteur and his assistant, Dr. Grancher, have been aided for some time past by Dr. Terrillon, Dr. Roux, Dr. Chantemesse, and Dr. Charrin.

With regard to the fresh experiments on dogs, an objection to the inoculation of human beings after being bitten might be raised on the ground that the immunity of animals treated before being bitten had not been sufficiently demonstrated after their undoubted infection by the virus. In reply to this objection M. Pasteur points to the immunity of dogs after trepanning and intra-cranial inoculation with the virus of ordinary street rabies. Trepanning is the surest method of infection, and its effects are constant. The first experiments on this point, dating from August 1885, had but partial success. They were resumed during the last few months, with certain modifications which produced the best results. The vaccination is begun the day after inoculation, and proceeded with rapidly, the series of prophylactic virus being all administered within twenty-four hours and even in a shorter period, and then repeated once or twice at intervals of two hours. The failure of Dr. Frisch, of Vienna, in experiments of this kind is due to the slow process of vaccination adopted by him. Success can be secured only by the rapid method here described. The immunity conferred under such conditions is the best proof of the excellence of this method.

REPORT ON THE CHARLESTON EARTHQUAKE[1]

THE earthquake of August 31, which, from the locality in which its greatest power was displayed, will generally be known as the "Charleston Earthquake," was, perhaps, the most notable disturbance occurring within the limits of the United States of which we have any knowledge. It is entitled to this rank both on account of the wide area over which it was distinctly felt, and of the magnitude of the disaster which it caused in the immediate vicinity of the point of maximum intensity.

The earthquake consisted of a series of seismic disturbances which began in slight but distinctly noticeable tremors occurring on August 27 and 28, at the town of Summerville, about twenty-five miles north-west of Charleston, South Carolina.

The shock of greatest violence occurred a little before ten o'clock on the night of Tuesday, August 31. It was followed by several of lesser magnitude on that night, and during the succeeding three or four weeks. The great shock began in the city of Charleston within a few seconds of 9.51 p.m., 75th meridian time. The duration of the vibratory motion of the earth at that point was probably about forty seconds; the motion at first being moderate, but increasing with great rapidity during the last ten or fifteen seconds.

All of the loss of life and property during the whole series of disturbances is to be attributed to this first shock. Five minutes later another occurred, and ten minutes later still another; the latter being of considerable violence, but neither alone would have done any damage. The same may be affirmed of the succeeding series of disturbances, which, with greatly diminished intensity and at increasing intervals of time, continued to maintain the conditions of alarm and terror into which the people of the afflicted locality were naturally thrown by the first disturbance. Although some injury to buildings resulted from these after shocks, it is tolerably certain that in all such cases displacement and fracture had taken place in the great shock; the lesser disturbances simply finishing what had then been nearly completed.

The origin of the disturbances, appears to have been somewhere below a point fifteen or twenty miles north-west of Charleston; that is, in the neighbourhood of the town of Summerville. A chart of provisional co-seismal lines drawn by Mr. Hayden of the Geological Survey, and published in *Science* for September 10, seems to locate this centre somewhat further north than the point indicated above. At the time of its construction, however, information from many points was lacking, and that which was at hand was admittedly doubtful in some degree.

Reference is made later to the iso-seismal chart which accompanies this Report, and which indicates that the origin was near the point referred to above. Strong proof of this is also furnished in the intensity and character of the disturbance as shown by the effects which were still visible when an examination was made a few days after the principal shock. The appearance of the brick piers upon which many houses in Summerville rest was such as to justify the conclusion that the principal component of the motion at that point was vertical, and it was evident that the destruction of buildings was much less than would have resulted from a horizontal movement equal to that which had taken place in Charleston and elsewhere in the neighbourhood.

Another fact of importance is that in the vicinity of Summerville the disturbances preceding that of August 31 took place, and here they have been most numerous and most persistent. Indeed, at the present writing, nearly a month after the first perceptible shock, they still occur at irregular intervals varying from a few hours to a few days. Only the most violent of these have been felt as far as Charleston.

Nearly all the movements in Summerville and vicinity have been accompanied by, and, indeed, generally preceded by, a low rumbling sound, lasting one or two seconds, and not unfrequently this sound, always unmistakable in its character, was neither accompanied nor followed by a perceptible movement. This was a common occurrence at Summerville and in the immediate vicinity, and it was found that among several observers there would be no agreement upon the direction from which the sound appeared to come.

Chart of iso-seismal lines.

At a distance from ten to fifteen miles from Charleston in the direction of Summerville some of the most curious and interesting effects of the disturbance were to be seen. These were the "sand craters" and crevices, out of which extensive eruptions of sand and water had taken place on the night of August 31. The craters thus formed varied in size from an irregular oval, twenty-five feet long by fifteen feet wide, to shallow cones not over an inch in diameter and beautifully symmetrical in form. The area surrounding these openings was generally flooded with sand, often acres in extent, to a depth varying from a fraction of an inch to fifteen and eighteen inches. About the larger cavities the average depth was probably not less than six inches, and the area covered often an acre or more. The flow of sand was unquestionably only an incident to the outflowing of vast quantities of water, the greater part of which disappeared within a few hours after its appearance. The few crevices or "cracks" in the earth which were found were in character and origin similar to the "craters," being long and narrow openings, through which water with sand had been ejected.

It was difficult, in fact quite impossible, to obtain reli-

[1] By Prof. T. C. Mendenhall, Assistant. From the *Monthly Weather Review*, U.S. Signal Service, August 1886.

able information concerning the nature of this phenomenon at the moment of its occurrence. The locality in which it was principally exhibited is near a station on the South Carolina Railway, between Charleston and Summerville, known as "Ten-mile Hill." It is thinly populated, and almost entirely by negroes. Several persons who pretended to have been eye-witnesses of the outburst gave widely different testimony as to its character. According to one account, the water and sand from one of the "geysers" spouted to a height greater than that of a telegraph pole and continued to flow for four or five hours. Another, and apparently an equally credible witness, declared that the stream reached a height of six or eight feet, and that the flow continued four or five minutes. The latter statement is probably nearer the truth than the former.

A few instances of sand eruptions were found in the city of Charleston, and a few also at Summerville, and at the latter place water continued to flow from one of the openings for several days after the first shock.

It is important to observe that in no case was it found that the water thus issuing from the earth was hot or noticeably above the temperature of water in shallow wells in the neighbourhood. Reports of boiling water having been thrown up were very numerous, but no evidence that the water was really hot appeared. The use of the word "boiling" doubtless grew out of the appearance of the water as it issued from the openings, and was probably used by eye-witnesses to describe this appearance with no reference whatever to temperature.

There were also reports of the appearance of blue flames in the neighbourhood of these eruptions, but no reliable testimony to their existence could be obtained. There was also a report that was circulated extensively through the medium of the press of the country that two or three showers of hot stones had fallen upon and near the office of the *Charleston News and Courier*. An examination of some of these shortly after they had fallen forced the conviction that the public was being made the victim of a practical joke.

In the city of Charleston about forty lives were lost. The greater number of casualties resulted from injuries sustained by persons who were either in the street at the time of the shock or who rushed out and were caught by the falling debris. No adequate description of the injury to property can be given in this place, and, indeed, the results of this earthquke have been so thoroughly considered in the public press that note is unnecessary.

While there was probably not a single house in the city which was not in some degree affected by the shock of August 31, there was naturally great diversity as to the extent of the damage in different localities. Some parts of the city are built upon what is called "made land," resulting in many cases from the filling up of old creek bottoms and from other extensive levelling and grading. A more careful study of these peculiarities and their distribution may lead to the discovery of some relation between local differences in structure and the areas of greatest destruction.

Unquestionably much is to be attributed to the difference in the character of the buildings themselves, and to the relation of their lines of greatest or least strength to the direction of the wave front. As was to be expected, buildings constructed of wood suffered much less than those of brick. The interior of wooden buildings, however, would often exhibit a scene of total destruction, furniture, book-cases, &c., having evidently been moved with great violence. A very brief examination of injured buildings sufficed to establish, in a general way, the principal direction of the movement, which was probably in a north-west and south-east line.

The probability of the destruction of a building depends so largely on conditions other than the amplitude or direction of the vibration of the earth particle that the study of destroyed or damaged structures can yield little exact information concerning these elements. The displacement of bodies of simple form and structure, lying near to or upon the surface of the earth itself, is a vastly more reliable index of the direction and intensity of the disturbance. In the churchyards of Charleston many instances of displacement and overturned monuments, columns, urns, &c., were found. These were examined with some care, and a careful study of the results may bring out some information concerning the dynamics of the earthquake. A cemetery containing many pyramidal or cylindrical shafts resting upon flat stone bases is tolerably certain, when disturbed by an earthquake, to exhibit not only displacement but also instances of twisting about a vertical axis; cases of this kind were numerous at Charleston. Such rotations by no means imply a similar gyratory motion of the earth, as it is well known that they may result, and doubtless always do, from vibratory motions in a single plane. It was not at all uncommon to find two columns, very near to each other, twisted in opposite directions.

A table was given containing a *résumé* of information received at the office of the Chief Signal Officer from regular observers of the Service and from a number of voluntary observers. The place, time, supposed direction, duration, and estimated intensity were given. Much discrepancy is observable in the records of time. Confusion is especially great in a few portions of the country in which so-called "local time" is still adhered to. Whenever "standard time" is known to have been used reduction has been made to that of the 75th meridian. In a few cases, however, no reasonable supposition can explain the discrepancies. Such records must be erroneous.

A study of this column will show the great importance, in making such observations, of determining the error of the clock or watch at the earliest possible moment by comparison with the time of some known meridian. It must be said, however, that the extended use of standard time has rendered these results vastly more accurate than they otherwise would have been. Telegraphic time-signals are now within the reach of most people, and during the past two or three years a great improvement in the accuracy of time-keeping among the people has taken place.

The direction of the movement recorded against each station is that given by the observer. As it is based in many instances on the motions of swinging objects, or easily movable objects, it is of necessity often erroneous. In the absence of correct instrumental records, however, such observations are of value. The numbers expressing the intensity of the disturbance were applied at this office, from descriptions furnished by observers, according to a scale adopted by the Director of the Geological Survey.

This scale is as follows:—

No. 1. Very light. Noticed by a few persons; not generally felt.

No. 2. Light. Felt by the majority of persons; rattling windows and crockery.

No. 3. Moderate. Sufficient to set suspended objects, chandeliers, &c., swinging, or to overthrow light objects.

No. 4. Strong. Sufficient to crack the plaster in houses, or to throw down some bricks from chimneys.

No. 5. Severe. Overthrowing chimneys and injuring the walls of houses.

With these intensity numbers an attempt has been made to plot a chart of iso-seismal lines, or lines of equal intensity. The result is shown in the chart. Nothing short of the use of well-constructed seismographs can furnish satisfactory measures of the amplitude of vibrations of the earth particle or the maximum velocity of the same, but in the absence of records of such instruments, this chart, or a more perfect one constructed upon the same plan, will afford opportunity for study.

In conclusion, it ought to be stated that this brief review of the Charleston earthquake must be regarded only as an attempt to place some of the leading facts upon record, for the benefit of the readers of the *Monthly Weather Review.* It is in no way intended to anticipate the investigations now in progress by the United States Geological Survey, a full report from which, based upon all attainable information, will be looked for with great interest.

THE SIMILARITIES IN THE PHYSICAL GEOGRAPHY OF THE GREAT OCEANS[1]

AT the outset Mr. Buchanan reminded the audience of the similarities observed in the eastern and western continents, especially in their southern extremities. Such similarities in corresponding localities had been called homologous geographical features, in imitation of the homologies of comparative anatomy, and they had received much attention from students of geography. A remarkable group of similarities of this kind is to be found in the arrangement of inclosed seas lying to the northward of the three southern continents. To the northward of South America there are the Gulf of Mexico and the different basins of the Caribbean Sea; to the northward of Africa there are the Mediterranean with its different basins, and on the north-east the Red Sea; and to the northward of Australia there are the well-known seas of the Eastern Archipelago. These seas are bounded on all sides by islands and insular groups, and they are in continuous connection with two oceans, the Pacific and the Indian. The African seas are bounded entirely by continental land and communicate directly with two oceans; but in the limited sense that one sea, the Red Sea, communicates with the Indian Ocean by a single channel, and the Mediterranean Sea with the Atlantic, likewise by a single channel. Finally, the American seas are all in continuous communication with only one ocean, the Atlantic, the continental barrier towards the Pacific being continuous.

It is not unworthy of remark that the great depths (over 4000 fathoms) of the Atlantic and the Pacific Oceans occur immediately to the northward of these groups of seas, and in the western sinus of the northern portions of both oceans; while the greatest depression of the continental land, the region of the Dead Sea, is found similarly situated with regard to Africa. The analogy here, however, does not hold good all through, because it is a mere accident of climate that this area does not form a large and not excessively deep fresh-water lake.

The seas of the Malay Archipelago and those of the West Indies have important functions in the physical geography of the oceans, as they receive the warm dense water of the westerly-running equatorial currents of the Pacific and the Atlantic Oceans. The Pacific current finds no obstacle in the chains of islands which bound the Malayan seas, and is able to pass freely through into the Indian Ocean; while the Atlantic current is stopped by the continuous continental barrier of South America, and the head of water thus produced is relieved by the overflow of the Gulf Stream all the year round. Although there is no static barrier, in the shape of continuous land, to the westerly Pacific current, there is, during one season of the year, a kinetic one, furnished by the prevalence of the south-west winds during the monsoon season. These furnish the intermittent *kuro siwo.* The main cause of the westerly equatorial current is the propulsive action of the trade winds.

These winds have also great evaporating power; and, by making the surface water salter, they furnish the mechanical means of propagating the surface heat into the deeper layers of the ocean. Hence the leading characteristic of the westward or leeward regions of the intertropical oceans is water of considerable density and of high average temperature in the sub-surface layers. This characteristic is seen most clearly in the Atlantic, where there is no communication with another ocean. In the Pacific the non-continuous boundary neutralises to some extent this effect, and gives to the eastern parts of the Indian Ocean a borrowed leeward character, independent of its own climate. A secondary consequence of a leeward position in the ocean, and due to the above-mentioned characteristics of the temperature and density of such water, is the prevalence of coral formations in the western regions of the Atlantic and Pacific, and, owing to the mixture of conditions, in both eastern and western regions of the Indian Ocean.

Continental homologies, or similar features in corresponding localities, are found on the western as well as on the eastern sides of the continents. One of the most striking is the resemblance of the Gulf of Guinea on the African coast with the great Central American bight stretching from Cape St. Lucas at the extremity of the Californian Peninsula, by Panama, to the mouth of the Guayaquil River, and with the unnamed bight in the Indian ocean bounded continentally by the north-west coast of Australia and insularly by the chain of islands stretching from the Peninsula of Malacca to Australia. Oceanically these bights are homologous. It is in them that the beginnings of the westerly-running equatorial currents are to be found, and perhaps more important still, it is in them that the easterly-running counter equatorial currents end. They are to be found in each of the three oceans, and generally on the northward side of the axis of the westerly-running current. In the Atlantic it is best known by its eastern portion, the Guinea current.

The observations here recorded of the Guinea current, a hitherto unexplored region of the ocean, were made on board the steamship *Buccaneer*, at the invitation of the owners, the India-rubber, Gutta-percha, and Telegraph Works Company, of Silvertown, and were carried out during a survey for a telegraph cable from Sierra Leone to St. Paul de Loanda. From a diagram showing the variation of salinity of the surface water of the Guinea current, with distance from the coast, it appeared that for a considerable distance along the Guinea coast the salinity of the surface water was an almost accurate test of the proximity of the land. The Guinea current starts in mid-ocean, but it is most constant near the African coast. The density of the water is low, its temperature high, and its velocity, especially in-shore, is sometimes as great as three miles an hour. It varies somewhat with the season.

Bottle experiments showed an average rate of fifteen miles per day in the months of January and February, for a thousand miles along the coast. In March, the *Buccaneer* experienced no easterly current, and in connection with this absence of easterly currents off the coast may be taken the very remarkable under-current which is found setting in a south-easterly direction with a velocity of over a mile per hour at three stations almost on the equator, and to the northward of the Island of Ascension. For the double purpose of examining the currents and of obtaining a large specimen of the bottom, the *Buccaneer* was anchored in 1800 fathoms of water by means of an ordinary light anchor fitted with a canvas bag to receive the mud which would otherwise fall off the flukes on its being weighed. While the ship was lying thus at anchor, the surface water was found to have a very slight westerly set. At a depth of 15 fathoms there was a difference, and at 30 fathoms the water was running so strongly to the south-east, that it was impossible to make observations of temperature, as the lines, heavily loaded, drifted straight out, and could not be sunk by any weight the strain of which they could bear. In the Pacific the counter equatorial current in the open ocean was well observed by the

[1] Abstract, by the Author, of a Paper read at the meeting of the Royal Geographical Society on Monday, November 8, by Mr. J. Y. Buchanan.

Challenger on her voyage from Hawaii to Tahiti. Her observations were illustrated by two diagrams, one showing the direction of the current, and the other the distribution of temperature and density in the upper layers of the water traversed. The easterly current was found between the parallels of 5° N. and 10° N., there being two streaks of maximum velocity, one between 7° and 8° N., and the other between 9° and 10°. In the former the mean daily set was 54 miles; in the latter it was probably quite as high, but it could not be accurately determined, as the ship passed from westerly to easterly current in the course of the 24 hours, and the observed current of 20 miles represented the difference of the two. The streaks or axes of strong easterly current are sharply defined by areas of abnormally low surface density. The whole of the area of easterly-running water has a comparatively low density, but where there is a sudden acceleration of its velocity, there is a correspondingly sudden drop in its density, so that the existence of a strong easterly current in equatorial regions may be guessed with great probability by the use of the hydrometer. The diagram showed also in a very marked way the protective action of the fresh surface water in preventing the penetration of heat into the lower layers of the water. A temperature of 60° Fahrenheit is found here at a depth of 50 fathoms from the surface, while in the westerly-running current, a little further south, the same temperature occurs at a depth of over 100 fathoms. In this region there are great inequalities in the density of layers of water at the same depth and within a short distance of each other. Thus, if the column of water between 20 fathoms and 70 fathoms from the surface be considered, its weight at the station where the westerly-running equatorial current prevails is only 88 per cent. of its weight under the counter equatorial current, the distance between them being not more than 200 miles. This disturbance of statical equilibrium must be balanced by circulation of water between the localities, and hence the violent and conflicting currents observed in these regions. The study of the currents of equatorial regions would well repay the trouble of the investigation. The counter equatorial current is particularly interesting, and its dynamics obscure. Its range is very superficial, and its physical conditions can be studied without the elaborate and costly equipment required for the research of oceanic depths.

To the north and to the south of the equatorial bights of the western shores of Africa and America we have a remarkable similarity in the distribution of temperature in the coast waters. The transition from equatorial heat to extratropical cold is very marked: on the North American shore, at Cape St. Lucas, the southern extremity of the Californian peninsula; on the North African, at Cape Verd; on the South American shore, at Cape Blanco; and on the South African, at Cape Frio. In rounding Cape St. Lucas the temperature was observed to fall from 75° to 65° F. in less than an hour; and a similar difference of temperature was found in rounding Cape Blanco between Payta and the Guayaquil river. On the Morocco coast the water is found to have a temperature quite 10° lower than is found twenty miles to sea. These sharp transitions are found only close inshore, and they have usually been attributed to surface currents from higher latitudes. This explanation is at variance with the observations of navigators on the coasts, who do not notice any currents which would be strong enough to bring water many hundreds of miles under a burning sun without sensible rise in temperature. The occurrence of these coast areas of abnormally cold water is explained when we recognise that they are the windward shores of the oceans. The trade winds blow from them towards the equator, and in doing so mechanically remove water, which has to be supplied from the readiest source. This source is the deep water lying off the continental coasts, which is supplied by a gradual drift of cold water from high latitudes. Hence, though the low temperature of the coast waters referred to is due to the cold of high latitudes, it is not supplied by a long coast Polar current, but by a short vertical one. This view was very strongly supported not only by the temperature of the water, but by its other characteristics, especially colour. The outside ocean water is of an intense ultramarine blue; the coast water off Mogador had the clear olive-green colour met with constantly in Antarctic seas. The same is observed on the west coast of North and South America, and it would be of the highest interest to have these waters investigated from a biological point of view. No waters in the ocean so teem with life as those on the west coast of South America. A bucket of water collected over the side is turbid with living organisms, the food of countless shoals of fish, who, in their turn, afford prey for innumerable schools of porpoises. One remarkable school which accompanied the ship for some time consisted entirely of females, each accompanied by a calf following in her wake and mimicking her every movement. Along with abundance of life this coast unites facilities for investigating it. At every port there are plenty of shore boats anxious for a fare, and with a tow-net and a few bottles a naturalist might make a rich collection of the shore-water fauna of the coast in one trip from Valparaiso to Panama.

The most remarkable confirmation of the view that the cold water on the windward shores is due to a submarine source has been quite recently supplied by the observations of Capt. Hoffmann, of the German man-of-war *Möwe*, on a voyage from Zanzibar to Aden. He kept close to the coast as far as possible, and observed a very uniform surface temperature of 78° to 80° F. from Zanzibar to Cape Warschek, when it began to fall, and remained at a temperature of from 60° to 65° F., until Cape Guardafui was reached, when the temperature went up rapidly to 86°. The minimum temperature observed was 59° F., and Capt. Hoffmann calls particular attention to the dark-green colour of the water, and in speaking of its low temperature he recognises that its source can only be the deep water in the neighbourhood, as the surface water on both sides has a temperature bordering on 80° F. The *Möwe* passed through these seas in the month of July, when the south-west monsoon is blowing most strongly, and at this season the Somali coast is a pronounced windward shore, and exhibits the same characteristics as the windward shores of Morocco or South America. The coral growths, too, which are so abundant north and south of it are here quite absent, thus accentuating the eastern or windward character of the shore.

NOTES

THE following is the list of selected names to be submitted to the Fellows of the Royal Society at the forthcoming anniversary meeting (November 30) for election into the Council for the ensuing session:—President: Prof. George Gabriel Stokes, M.A., D.C.L., LL.D.; Treasurer: John Evans, D.C.L., LL.D.; Secretaries: Prof. Michael Foster, M.A., M.D., Lord Rayleigh, M.A., D.C.L.; Foreign Secretary: Prof. Alexander William Williamson, LL.D.; other Members of the Council: Prof. Robert B. Clifton, M.A., Prof. George Howard Darwin, M.A., LL.D., W. T. Thiselton Dyer, M.A., Prof. David Ferrier, M.A., Edward Frankland, D.C.L., Arthur Gamgee, M.D., Archibald Geikie, LL.D., Prof. Joseph Henry Gilbert, M.A., John Hopkinson, M.A., D.Sc., J. Norman Lockyer, F.R.A.S., Sir Lyon Playfair, K.C.B., LL.D., Prof. Bartholomew Price, M.A., Prof. Pritchard, M.A., Admiral Sir George Henry Richards, K.C.B., Prof. Arthur Schuster, Ph.D., Philip Lutley Sclater, M.A., Ph.D.

IN the third volume of Ray's "Historia Plantarum" there is a list of plants collected in the Island of Luzon by George Joseph

Camelli. This botanist was a member of the Society of Jesus, and was born at Brunn, in Moravia, April 21, 1651; after a life spent for the most part in the Philippines, he died at Manila, May 2, 1706. Linnæus commemorated him in the genus Camellia, and the introduction of this well-known plant into Europe is generally attributed to him. The manuscript transmitted by Camelli to Ray was accompanied by a large number of drawings, part only of which Ray seems to have been able to afford the expense of publishing. We learn from the *Comptes rendus* of the Société Royale de Botanique de Belgique for October 9, 1886, that the whole of the drawings still exist in a folio volume in good preservation in the library of the Jesuits' College at Louvain. It contains 257 autograph plates, with 556 figures of plants, and three plates, with nine figures relating to zoology. It was purchased at the sale of the library of Antoine Laurent de Jussieu (February 6, 1858), in whose handwriting it is carefully annotated, and was presented to the Jesuit College by Count Alfred de Limminghe.

DR. WALTER L. BULLER, C.M.G., F.R.S., the well-known New Zealand ornithologist, has been promoted to the Knighthood of the Order of St. Michael and St. George.

THE honorary degree of D.Sc. has been conferred by the Senate of the Royal University of Ireland upon the Rev. S. J. Perry, F.R.S., and Prof. John Perry, F.R.S.

THE Committee appointed by the Prince of Wales to assist in framing a scheme for the proposed Imperial Institute is ludicrously inadequate and unrepresentative. The President of the Royal Academy appears, but why is the President of the Royal Society omitted? Surely science will have far more to do with such an institute than art. The only representative of science is Sir Lyon Playfair, and he has been appointed probably more on account of his connection with the 1851 Exhibition than with science. If the Committee is to gain the confidence of the public it must be of a very different character.

IN view of the progress achieved of late in the domain of celestial photography, the French Academy of Sciences has decided to propose that an International Conference be held in Paris next spring to make arrangements for the elaboration of a photographic map of the heavens to be simultaneously executed by ten or twelve observatories scattered over the whole surface of the globe.

ACCORDING to the Report of the Director of the Leander McCormick Observatory of the University of Virginia for the year ending June 1, 1886, the buildings and instruments are in excellent repair; the great 45-feet dome revolving fully as easily as when first erected. The Parkinson and Frodsham clock, formerly belonging to the Physical Laboratory, has become the property of the Observatory. It is now in Washington, in the hands of a jeweller, to be cleaned and recased. The great equatorial has been chiefly employed in the examination and sketching of southern nebulæ. The nebula in Orion and the Trifid and Omega nebulæ have received special attention. 351 observations of miscellaneous nebulæ have been made, resulting in 226 drawings, and the discovery of 233 nebulæ which are supposed not to have been hitherto detected. The features seen indicate that the performance of the instrument employed surpasses that of any of the great reflectors which have been used in the examination of nebulæ, the examination of complicated structures seldom failing to show features not noticed elsewhere. Only a few nights have been suited to the micrometrical measurement of double stars. Seventy-six observations have, however, been made of stellar pairs, nearly all of which are close and difficult. According to the Director, Mr. Ormond Stone, the past year has been, without exception, the poorest for astronomical observations which he has ever known. Not only have there been an unusual number of cloudy nights, but even on clear nights the definition has been almost always extremely poor. The Observatory is open to the general public every day, except holidays and Sundays, between 2 and 5 p.m. It is also open to a limited number of visitors once each month at 8 p.m.

BY the kindness of the under-mentioned gentlemen, lectures will be delivered as follows before Christmas at the Royal Victoria Hall and Coffee Tavern:—November 16, Mr. A. T. Arundel (Madras Civil Service), "Glimpses of India and its People"; November 23, Mr. Arthur Brown, "The Yellowstone Region"; November 30, Prof. A. W. Rücker, "Early History of the Earth and Moon"; December 7, Rev. W. H. Dallinger, "Plants that Prey on Animals and Animals that Fertilise Plants"; December 14, Prof. Boyd Dawkins, "Introduction of the Arts into Britain." With regard to the classes now held in the building, about eighty students have joined, many of whom are attending more than one class, and it is expected that fresh classes will shortly be started. A very satisfactory feature of the matter is that the students are genuine artisans, who would not otherwise have good teaching within their reach.

IN the form of a leaflet reprinted from *Humboldt* (Band v. Heft 10), M. Habenicht, of Gotha, sends us a "Contribution to the Morphology of the Kosmos." Although his emendation of the nebular hypothesis can scarcely be called an improvement upon it, it is one among many symptoms of the breaking up of ideas on the subject, and their tendency to flow into new channels. M. Habenicht remarks that, in the primitive nebula, "the laws of Nature slumber." For the convenience of the majority of speculators on origins, their awakening should be indefinitely postponed. His theory of planetary formation depends upon disparity of temperature, the inner side of the originating ring being warmed by the central body, while the outer side radiates freely into space. The result is unequal contraction occasioning rupture at the weakest place, whereupon a remarkable process ensues. Through the *tightening* of its outer surface, the ring coils up from the outside into two spirals containing very different quantities of matter, which eventually rush together from opposite directions, and coalesce into a planet. This dual origin is visible in the dissimilarity of the terrestrial hemispheres, as well as in certain aspects of Mars, and in some rare glimpses by Dawes of the disposition of light and shade on Jupiter's third satellite. The analogy is even carried out, we are told, in the organic world, from the tiny seed-leaves of the embryo-plant to the symmetrical yet not strictly balanced arrangement of limbs in the highest order of beings. But the planet-producing rings, to behave as M. Habenicht supposes them to have behaved, should have possessed rather the qualities of caoutchouc than those of any known or imaginable "nebulous" stuff.

UNDER the title of "Sea-Level and Ocean-Currents," Prof. J. S. Newberry sends the following letter to *Science*:—"Put-in Bay Island, October 16, 1886.—At 11 o'clock Thursday evening, the 14th inst., I witnessed here a remarkable fact, the effect of the late tremendous wind-storm. This commenced about 7 a.m., and began to let up at 11 o'clock in the evening, or a little later. I then went down to the shore in front of my house, and found the lake lower than the average by fully 6 feet! This is the greatest depression from such cause I have noticed during a residence here of nearly twenty-four years. We have not, within this period, had such a high wind steadily continued for so long a time. The captain of the steamer *Chief Justice Waite*, running between Toledo and the islands, reports the fall of water-level at Toledo as about 8 feet." In discussing the general question with reference to previous correspondence, Prof. Newberry says:—"The question is, not whether the wind has the power of raising the water-level on a coast, but whether wind-friction can, in the great equatorial belt and in the track of the Gulf Stream, produce the flow of water which is there observed. The striking cases of the power of wind to heap water on coasts, and to move bodily great masses of it in lakes, are only interesting and relevant as demonstrating the sufficiency of wind-friction to produce broad and rapid surface-currents. This conceded, and the case is won, because, in the lakes and open ocean, like causes produce like effects. Wind of given velocity raises in both places waves of equal height in equal times: against these waves the wind presses in the direction of its flow, with no opposing force. As a consequence, the roughened water-surface, from greatly increased friction, is moved bodily forward just as though impelled by the paddles of a revolving-wheel. This surface-flow is in time communicated to underlying strata, and, if the wind continue to blow in the same direction, ultimately a large body of water will be set in motion; in other words, an ocean-current will be produced. There is no escape from this conclusion. The great truth remains that wind-friction can produce ocean-currents."

A SHOCK of earthquake of a more or less severe nature was felt at noon on November 5 at Washington, Richmond, Wilmington, Raleigh, Augusta, Charleston, Savannah, Macon, and other places in North and South Carolina. At some points the seismic disturbance was the severest since August 31. A shock of earthquake was also felt at Greenville, Alabama, on Friday last. The captain of a vessel which has since arrived at Charleston reports having experienced a seismic disturbance on that day while at sea.

PROF. JOHN MILNE, of Tokio, Japan, writes with reference to Prof. Ewing's article on seismographs in NATURE, vol. xxxiv. p. 343, that the instruments therein described represent the state of general knowledge of the Seismological Society of Japan with regard to seismometry at the time of Prof. Ewing's departure from that country. With the exception of one or two which have been modified, a set of instruments like those recommended by Prof. Ewing are, so far as Japan is concerned, quite obsolete. A very much better form of instrument is Prof. Milne states, now in use in the Government observatories and throughout the country.

IN a paper by the Hon. Ralph Abercromby, reprinted from the *Quarterly Journal* of the Meteorological Society, on the origin and course of the squall which capsized H.M.S. *Eurydice* on March 24, 1878, the author concludes as follows:—"The squall which capsized H.M.S. *Eurydice* was one belonging to the class which is associated with the trough of V-shaped depressions. The line of this trough was curved like a scimitar, the convexity facing the front. The whole revolved round a point near the Scaw, in Denmark, like the spoke of a wheel. For this reason the portion of the squall over the east of England moved only at the rate of 13 miles an hour, while the western portion travelled nearly 50 miles in an hour. The portion which struck the *Eurydice* was advancing at the rate of 38 miles an hour. The length of the squall over England was more than 400 miles, but only 1 to 3 miles in breadth. Hence we have the picture of a scimitar-shaped line of squalls, 400 miles long and about 2 miles broad, sweeping across Great Britain at a rate varying from 13 to 50 miles an hour. The V-depression was one of an uncommon class, in which the rain occurs after the passage of the trough, and not in front of it, as is usually the case. The weather generally for the day in question was unusually complex, and of exceptional intensity, and for this reason some of the details of the changes cannot be explained."

AT a recent meeting of the Niederrheinische Gesellschaft für Natur- und Heilkunde at Bonn, Dr. Gurlt described a fossil meteorite found in a block of Tertiary coal, and now in the Salzburg Museum. He said it belonged to the group of meteoric irons, and was taken from a block of coal about to be used in a manufactory in Lower Austria. It was examined by various specialists, who assigned different origins to it. Some believed it to be a meteorite; others, an artificial production; others, again, thought it was a meteorite modified by the hand of man. Dr. Gurlt, however, came to the conclusion, after a careful examination, that there is no ground for believing in the intervention of any human agency. In form, the mass is almost a cube, two opposite faces being rounded, and the four others being made smaller by these roundings. A deep incision runs all round the cube. The faces and the incision bear such characteristic traces of meteoric iron as to exclude the notion of the mass being the work of man. The iron is covered with a thin layer of oxide; it is 67 mm. high, 67 mm. broad, and 47 mm. at the thickest part. It weighs 785 grammes, and its specific gravity is 7·75; it is as hard as steel, and it contains, as is generally the case, besides carbon, a small quantity of nickel. A quantitative analysis has not yet been made. This meteorite resembles the celebrated meteoric masses of Saint Catherine in Brazil and Braunau in Bohemia, discovered in 1847, but it is much older, and belongs to the Tertiary epoch.

DR. DOBERCK, the Government Astronomer in Hong Kong, has published a pamphlet entitled "The Law of Storms in the Eastern Seas," containing the practical results of investigations of about forty typhoons, continued during three years. He divides typhoons into four classes, according to the paths which they usually follow:—(1) Those which cross the China Sea and travel either in a west-north-westerly direction from the neighbourhood of Luzon towards Tonquin, passing south of, or crossing the Island of Hainan; or, if pressure is high over Annam, they travel first westward and then south-westward. These, which occur at the beginning and end of the typhoon season, can generally be followed for five or six days. (2) The second class are most frequently encountered, and their paths can be traced farthest. They generally travel north-westward while in the neighbourhood of Luzon, and either strike the coast of China south of the Formosa Channel, in which case they abruptly lose the character of a tropical hurricane, re-curve in the interior of China, and re-enter the sea to the north of Shanghai, pass across or near Corea, and are finally lost to the east-north-east. Typhoons of this class may pass up the Formosan channel, and re-curve towards the coasts of Japan, or they may strike the coast of China north of Formosa. A third of the typhoons belong to this class; they can be followed between five and twelve days, and are most common in August and September. (3) This class is probably the most numerous of all, although not so frequently encountered. Their path is along the east of Formosa, travelling northwards and passing near Japan. (4) Typhoons of this class pass south of Luzon, travelling westward. Their dimensions are very limited, and hitherto they have not been followed for more than a day or two. When a few hundred typhoons have been investigated, no doubt complete lists of the sub-classes of these four main classes will be obtained, and exceptional cases will be better understood. The pamphlet, which is largely written for the guidance of ship-masters and others, concludes with the remark that typhoons are of simpler construction, and their paths are more regular, than the storms of Europe. Typhoons are so violent near their centre that the whole disturbance is evidently ruled thereby; whereas storms in the North Atlantic and in Europe appear to be made up of a number of local eddies, some of which are by degrees detached from the chief disturbance and form subsidiary depressions. Dr. Doberck has not been able to ascertain the existence of a subsidiary depression in the China Seas during the last three years, and it is, therefore, doubtful whether they ever occur.

THE additions to the Zoological Society's Gardens during the past week include two Rhesus Monkeys (*Macacus rhesus* ♀ ♀) from India, presented respectively by Col. J. M. McNeile and Mrs. E. White; a Rose-crested Cockatoo (*Cacatua moluccensis*) from Moluccas, presented by Miss Townshend Wilson; twelve Barbary Turtle Doves (*Turtur risorius*) from Africa, presented by Mr. E. L. Armbrecht, F.Z.S.; four Copper-head Snakes (*Cenchris contortrix*), two Rattlesnakes (*Crotalus durissus*), a Hog-nosed Snake (*Heterodon platyrhinos*) from North America, presented by Mr. W. A. Conklin, C.M.Z.S.; a Long-nosed Snake (*Heterodon nasicus*) from Indiana, U.S.A., presented by Miss Catherine Hopley; a Fire-bellied Toad (*Bombinator igneus*) from Germany, presented by Mr. G. A. Boulenger, F.Z.S.; a Bactrian Camel (*Camelus bactrinus* ♂), bred in England, two Eleonora Falcons (*Falco eleonoræ*) from North Africa, a Macaque Monkey (*Macacus cynomolgus* ♂) from India, deposited; two Mantchurian Crossoptilons (*Crossoptilon mantchuricum* ♂ ♀), two Bar-tailed Pheasants *Phasianus reevesi* ♂ ♀) from Northern China, purchased; ten Barbary Turtle Doves (*Turtur risorius*), four Ring Doves (*Turtur communis*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

STELLAR PHOTOGRAPHY AT HARVARD COLLEGE.—Prof. Pickering has recently presented to the American Academy of Arts and Sciences an important memoir on the work in stellar photography which has been carried on at Harvard College, mainly by aid of an appropriation from the Bache Fund. The memoir commences with a brief sketch of the history of stellar photography, from its origination in 1850, when Mr. J. A. Whipple succeeded in obtaining a satisfactory daguerreotype of Vega with the Harvard 15-inch equatorial, the first stellar photograph ever secured. In 1857, the collodion process having then been introduced, Prof. G. P. Bond resumed the investigation, and showed that photography was capable of doing real work in the observation of double stars. In 1882 some preliminary experiments with a lens of 2½ inches aperture were made, and with such satisfactory results that in 1885 the work was resumed with a Voigtländer lens of 8 inches aperture, and about 45 inches focal length, that focal length having been selected that the photographs might correspond in scale to the maps of the "Durchmusterung." Of the three departments into which stellar photography may be divided, viz. star-charting, photographing star-trails, and spectrum photography, Prof. Pickering has chiefly interested himself in the two latter. Star-trails—the images, that is, produced on a plate when the telescope is stationary, or is not following the star with precision—are made exceedingly useful. It furnishes the best method of determining the magnitudes of stars photographically, and the average deviation of the measures of the brightness of circumpolar stars on different plates proved to be less than a tenth of a magnitude, a greater accordance than is given by any photometric method. It is Prof. Pickering's intention to obtain determinations of the brightness of all stars north of 30° S. decl. by this method, and the work is now nearly completed. One of the plates taken on November 9, 1885, incidentally affords conclusive evidence that Mr. Gore's Nova Orionis was then much less bright than it was on the night of its discovery, some five weeks later. By photographing on the same plate circumpolar stars near their upper and lower culminations, the means for determining the atmospheric absorption on the nights of observation have been secured. Prof. Pickering has also made some experiments on the applicability of photography to the transit instrument, and concludes that the position of a star may be determined from its trail with an average deviation of only 0·03s. Prof. Pickering also shows how star-trails may be made useful in determining the errors of mounting of the photographic instrument. Photographs of stellar spectra have been obtained by simply placing a large prism in front of the object-glass. The spectra of all the stars over an extended area are thus obtained at a single exposure; an exposure of five minutes giving the spectra of all stars down to the sixth magnitude in a region 10° square. The entire sky north of 23° S. decl. is to be examined in this way, and the work is now far on the way to completion. An exposure of an hour shows the spectra of stars down to the ninth magnitude. A photograph of the Pleiades in this manner brings out the interesting fact that, with very few exceptions, all have spectra of the same class—a circumstance which seems strongly to confirm the idea of a community of origin. The exceptions may not improbably lie at a considerable distance on this side or the other of the group, and should, as Prof. Pickering suggests, receive attention in any study of the parallax of the Pleiades. Prof. Pickering also here discusses several theoretical points of interest, one being the relation between the dimensions of the lens employed and the light of the faintest star that can be photographed with it. He concludes, on the whole, that, where the telescope follows the star with exactness, the limiting amount of light may be assumed as proportional to the aperture divided by the square root of the focal length. Three photographic plates accompany the memoir: the first showing the photographic instrument, the second the trails of a number of close circumpolar stars, and the third several specimens of photographs of stellar spectra, those of Vega, Altair, and of the Pleiades being amongst the number.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 NOVEMBER 14-20

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on November 14

Sun rises, 7h. 18m.; souths, 11h. 44m. 35·5s.; sets, 16h. 11m.; decl. on meridian, 18° 18′ S.: Sidereal Time at Sunset, 19h. 46m.

Moon (at Last Quarter November 18) rises, 17h. 54m.*; souths, 1h. 43m.; sets, 9h. 37m.; decl. on meridian, 18° 13′ N.

Planet	Rises	Souths	Sets	Decl. on meridian

Meteor Showers

November 14 is the date of the *Leonid* shower, R.A. 149°, Decl. 22° N.

THE EROSION OF THE ENGLISH COASTS

THE opening meeting of the present session of the Geologists' Association took place last Friday evening at University College, when an address was delivered by Mr. W. Topley, President of the Association and Secretary of the British Association Committee on Coast Erosion. The subject of the address was "The Erosion of the Coasts of England and Wales."

Mr. Topley, in his address, referred to the great service rendered to the country by Mr. J. B. Redman, who had given much attention to the question of coast erosion, and to whom the British Association Committee was greatly indebted. The speaker then proceeded, by the aid of diagrams and drawings on the blackboard, to describe the mode in which the sea acts on coasts of various kinds, and stated the rate at which erosion is taking place in different parts of the country. It was greatest along the coast of Holderness and Norfolk, where the sea gained on the land at the average rate of from 2 to 3 yards per year. But locally and during exceptional gales the rate was much higher. On January 30, 1877, parts of Norfolk lost an average of 3 yards for several miles, and near Bacton the loss was 15 yards. Typical instances of erosion were cited, among the places mentioned being Folkestone, Brighton, Worthing, Bournemouth, Westward Ho! and Pembrokeshire. The speaker then went on to describe the shingle beaches and their changes, and to discuss the effects of natural and artificial groynes. On the south coast of England the shingle travelled from west to east, and if left to itself it would form a natural protection along the greater part of the coast, and the average amount of erosion would be small. But in certain places land-owners, town-councils, and other corporations desired that there should be no loss of land, and they erected groynes to collect the shingle, and so robbed the coast to the east of its natural protection. Worthing was heavily groyned and the shingle largely collected, but just east of the town the coast was rapidly receding. Folkestone pier was a large groyne which had collected an extensive area of shingle on its west side; Copt Point and Eastwear Bay, once protected by a continuous band of shingle, were now nearly bare, and the coast was rapidly going. At Copt Point land was laid out for building, and roads were made; but the notice-board advertising "this desirable freehold building land," was seen half-way down the cliff. Natural groynes were sometimes recklessly destroyed, and this was the case at Hengistbury Head, where ironstone was quarried from the cliff and foreshore; the reef had held back sufficient shingle to protect the land to the west, but when the reef was removed, the shingle travelled on, and the land rapidly receded. Great damage was done by taking shingle for road metal, ballast, or other purposes. The amount so taken appeared small and unimportant because a single storm might throw up as much as might be taken in many months, but the aggregate amount so removed was enormous, and must tell in time. It had been estimated that the shingle removed near Kilnsea in twenty years represented a bank 3 miles long, 31 yards wide, and 6 feet deep. It was interesting to note that the erosion of that part of the coast averaged only from three-quarters of a yard to a yard and a half per year for some time before the shingle trade was so largely developed; but later on, owing to the loss of the shingle, the rate of erosion rose from 3 to 6 yards per year. The change might not be entirely due to the cause mentioned, but it clearly was so to a large extent. Although the Board of Trade had now stopped the practice at that part of the coast, it was still in full action in a large number of places. The speaker then passed to the consideration of the land gained from the sea. A great part of the material worn from the coasts of Holderness and Norfolk was carried into the estuaries of the Humber and the Wash, and there formed banks of sand and silt of great hindrance to navigation, but when reclaimed of great agricultural value. Recent estimates showed that the area of land thus made in the Humber and Wash was far in excess of that lost. Taking the whole coast-line of England, it was probable that the total area of land was as great now as it was 500 years ago. Although the general result of a survey of this question was less serious than was generally supposed, it was evident that greater control was requisite over the action of land-owners and public bodies along the coast. The powers now vested in the Board of Trade might be more rigorously and systematically applied, or fresh powers obtained. This was especially desirable along the south coasts, as there the damage done by reckless groyning was enormous, but the area of land now gained was small.

OBSERVATIONS ON HEREDITY IN CATS WITH AN ABNORMAL NUMBER OF TOES

IN 1883 I contributed an article to NATURE (vol. xxix. p. 20) upon this subject, giving an account of my observations from 1879 up to the date at which the paper was written. The last observation was concerned with a family of four male tabby kittens, all of which possessed the abnormality to a very marked extent. This was the first family produced by a female tabby (and slight tortoiseshell) cat which, when born, was the most abnormal form which had come under my notice, possessing two extra toes on all the paws, *i.e.* seven on each fore-paw and six on each hind-paw. The right paws of this cat were figured in

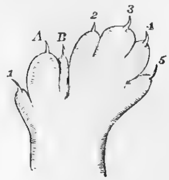

FIG. 1.—Right fore-paw from above, with extra toes.

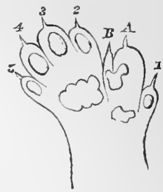

FIG. 2.—Right fore-paw from below, with extra toes.

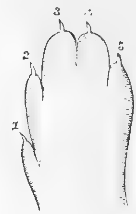

FIG. 3.—Right fore-paw from above, normal.

FIG. 4.—Right fore-paw from below, normal.

FIG. 5.—Right hind-paw from above, with extra toes.

FIG. 6.—Right hind-paw from below, with extra toes.

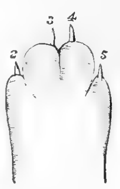

FIG. 7.—Right hind-paw from above, normal.

FIG. 8.—Right hind-paw from below, normal.

the paper referred to, together with the corresponding paws of a normal cat, for comparison. These figures are now reproduced in order to illustrate the present paper. I quote the description of the figures from the previous paper. "It is seen that the extra toes (in the fore-feet) are those labelled A and B (in Figs. 1 and 2), and they confer the extraordinary breadth upon the foot. The most recently added is B, which is still partially coalesced with A, and has but one pad in common with it (Fig. 2). . . . There is seen to be an extra pad behind the additional toes, of which there is no trace in the normal foot." In some families to be described, and also in two previously noted, the large extra toe, A, is present, while the insignificant pollex (Fig. 1, I) is absent, and thus the paw appears extremely broad, although with only the normal number of toes. In the hind-paws (Figs. 5 and 6) "there is little doubt that the innermost toe I is the hallux lost in the normal foot. . . . The second extra toe is that labelled A. . . . On the under side (Fig. 6) all the toes have separate pads, and there is an additional pad behind the extra toes," which is sometimes fused with that behind the normal toes.

This cat produced her first family, described in the previous paper, on July 10, 1883. Continuing the observations from that date, the next family (of four tabby kittens) was born in June 1884. (1) and (2) were normal—a male and a female. (3)—a female—possessed six toes on the fore-paws, each toe with a separate front pad, and a bifid hind pad (distinct from that for the other toes) to the two inner toes (I and A in Figs. 1 and 2); the toe shown in the figure and absent in this kitten is of course that marked B—the last to be added in all cases. The hind-paws possessed six toes each, as in the mother, and with the same arrangement of pads as in her left hind-paw, *i.e.* with separate front pads to each toe (as in Fig. 6), but with the hind pads for the extra toes I and A continuous with those for the four normal toes (unlike Fig. 6 in this respect). (4), a female, possessed seven toes on the right fore-paw; the front pads separate except in the case of those for the toes A and B, Fig. 2, which were slightly fused. The hind pad for the three innermost toes was quite separate from that for the others. This paw, in fact, almost exactly resembled that of the mother-cat on the same side, shown in Figs. 1 and 2. The left fore-paw possessed six toes, the small one marked B in Figs. 1 and 2 being absent. The pads were in other respects similar to those of the right paw. Thus the relative amounts of abnormality on the two sides are as with the mother, the preponderance being on the right side in both cases. But the difference is here greater in both directions, the right paw having rather more abnormality than in the mother, because of the less complete fusion between the front pads of the toes A and B, while on the left side the abnormality is much less than in the mother, in the complete suppression of the toe B. The hind-paws were as in the last kitten, and similar to the left hind-paw of the mother.

The next family (of three) was born September 22, 1884. (1), a female tabby kitten, was normal. (2), a female tabby kitten, possessed seven toes on the right fore-paw, with separate front pads to each toe and the hind pad as in Fig. 2. The innermost claw was double, the two divisions being arranged vertically one above the other, the lower being small and incomplete. In this respect, and in the separate front pad to the toe B, this paw is far beyond the mother's paw of the same side in abnormality. The left fore-paw possessed six toes, that marked B being absent. Otherwise the arrangement of pads was similar to that shown in Fig. 2. Hence this paw is more normal than that of the mother on the same side, and both fore-paws compare with those of the mother in the same manner as those of No. 4 of the last family, the only difference being the even greater abnormality of the right paw in the present instance. The hind-paws possessed six toes with separate front pads and continuous hind pads, as in the left hind-paw of the mother. (3), also a female tabby kitten, possessed seven toes on both fore-paws. The arrangement of pads on both paws was similar to that on the left fore-paw of the mother, except that the toe B could not be said to possess a front pad at all. The hind-paws were as in the last kitten and the left hind-paw of the mother.

The next family (of three) was born in September 1885. (1), a female tabby and slight tortoiseshell kitten, possessed the normal number of five toes on the fore-paws, but the foot appeared almost as broad as in the abnormal kittens. This was because the large extra toe (A in Figs. 1 and 2) was present while the much smaller pollex I was absent. The front pad of the large abnormal toe was also slightly bifid, so that there was some indication of the next small toe B. The hind-paws possessed five toes with separate front pads and fused hind pads. (2), a female tortoiseshell and tabby kitten, possessed fore-paws like those of the kitten just described. The right hind-paw was also similar, with five toes, but the left possessed six like the mother. The front pads were separate, as usual, on the hind-paws. (3), a female tabby and slight tortoiseshell kitten, with fore-paws having seven toes like the mother, and also resembling her in the difference between right and left. The right paw possessed most abnormality, and was more advanced than the mother, as all the toes—even that marked B—possessed separate front pads. On the left side, however, the toe marked B possessed no separate pad. The hind-paws were like those of the mother, possessing six toes with separate front pads. This kitten was given to a friend, and will be again referred to.

The next and last family (of four kittens) up to the present time was born about July 1, 1886. (1), a female tabby kitten, was normal. (2), a female tabby kitten, possessed five toes on the fore-paws, but the feet were very broad, because the large abnormal toe (marked A, Figs. 1 and 2) was present instead of the small pollex. The hind-paws possessed six toes like those of the mother. (3), a male sandy kitten, possessed seven toes on the left fore-paw, the innermost (pollex) being *exceedingly* small and rudimentary, while the right paw possessed only six toes, the pollex being absent, although both abnormal toes (A and B, Figs. 1 and 2) were present. In this kitten the difference between the sides is therefore the reverse of that in the mother. The hind-paws possessed six toes like those of the mother. (4), a male tabby kitten,—by far the most abnormal form which has yet come under my personal notice. Both fore-paws have seven toes, each possessing a separate front pad, while the claw of the small toe B is well formed and large, and its pad is large and quite distinct and separate from that of A. The claw of the pollex I on both sides is partially divided (towards the apex) into a large upper, and rather smaller lower, division. This tendency towards a vertical proliferation has been already described in one of the kittens of the family born September 22, 1884. In the hind pads this was also the most abnormal form yet seen, for, interior to the normal fused hind pads for the four normal toes 2, 3, 4, and 5, were arranged three pads forming an almost continuous series with each other and with those belonging to the four normal toes. These three pads diminished in size from within outwards, and the one behind the toe B was very small, and was somewhat separated from the others, and especially associated with the internal side of the fused normal pads. The hind pads for the toes I and A were fused, but a distinct furrow indicated the line of separation. There was no practical difference between the fore-paws of the right and left side. The right hind-paw possessed *seven* toes, or three more than in the normal animal. This is the first time that I have come across so great an abnormality in the hind-paws, although Mr. Vaughan remembers it on both right and left sides in two individuals. All the seven toes are large and distinct, and have separate front pads. Interior to the normal fused hind pads, and continuous with them, is an ill-defined series of three pads, irregularly diminishing in size towards the interior, and crowded together so that the innermost is not behind the innermost toe. The foot is somewhat deformed. The left hind-paw possesses the usual six toes with separate front pads and fused hind pads.

I now return to (3) of the family mentioned before the last—the highly abnormal female tabby which was given to a friend in Oxford. This cat produced a family (of four) on July 10, 1886. (1) and (2), both sandy male kittens, were normal; (3) and (4), both tabby female kittens, were like the mother, possessing seven toes on the fore-paws and six toes on the hind-paws. These two kittens were given to Prof. Meldola and Mr. W. White, and I trust that they will be frequently referred to in some future number of NATURE. I am now able to give a somewhat longer account of these two kittens. In Prof. Meldola's kitten the left fore-paw is somewhat less abnormal than the right, because the toe B is very small, although it possesses a front pad separate from that of A. Of course the pollex I has a distinct front pad. There is a single, although somewhat divided, hind pad for the three inner toes, separate from the normal pad behind the four outer digits. On the right side the toe B is large, but the arrangement of front and hind pads is the same as that on the left side. The hind-paws have large and distinct front pads on all the six toes of both sides, and the hind pads of the abnormal toes form a continuous series with those behind the normal digits.

The fore-paws of Mr. White's kitten are precisely similar in every respect, the toe B being much larger on the right side, and the arrangement of pads being exactly the same. The hind-paws only differ in the fused hind pads for the abnormal toes being somewhat separated from those behind the normal

Capitals used for those female cats which have produced families of which some note has been taken

"I., II.," &c. = generations

"1, 2," &c. = families

"i., ii.," &c. = kittens in each family

Dates and localities indicate times and places of birth of the families to which they are affixed

"F P" = fore-paw { the numbers after = toes

"H P" = hind-paw { the letters R or L before = right or left side

"F P 5 but abnormal" indicates that the small pollex is absent, but the large abnormal toe A in Figs 1 and 2 is in its place, making the paw abnormally broad, although with only the normal number of toes digits on the left side, while the two sets are continuous on the right paw, as in Prof. Meldola's kitten.

All the observations recorded in this paper were made in Oxford. The abnormality has now been observed through nine generations, and I have recorded notes of ten families, so that now there is sufficient material to present in a tabular form.

The notes given in this paper are much more complete than before, because the families were born in my own house or in that of a friend living near, who kindly gave me every opportunity of making notes. The results, however, would have been far more extensive if I had received intelligence of the birth of families in various quarters to which kittens had been sent.

I believe there is little doubt that the next period of three years will produce much better results in this way, for at the recent meeting of the British Association at Birmingham I exhibited the cats, and was able to give away three abnormal females to scientific gentlemen (Prof. Haddon, Prof. Meldola, and Mr. W. White) who I am sure will assist me by sending complete accounts of all the families born. I remarked in my last paper on the immense strength of heredity which was shown in the observations then recorded, remembering that the results were in all cases due to the mothers of the families. The continued observations now published serve to illustrate the same facts. As I said before, "it is practically certain that the fathers of the families have always been normal." There has, indeed, been an abnormal male cat in Oxford for the last two years—one of my kittens which I gave to Prof. Moseley for a museum specimen, and which has been kept in order that it may be quite mature. But this cat lives at some distance from my house and that of the friend to whom I gave the female kitten in 1885, and it has never been seen in our neighbourhood, while numbers of normal cats have been seen in company with our abnormal females. But nevertheless a family containing abnormal kittens was born in a house near that in which Prof. Moseley's cat is being kept, and of which, of course, the latter must be the male parent. Unfortunately, as in so many other cases, I was unable to obtain any data, and the kittens are, I believe, all dead.

We therefore see in these observations a proof of the extraordinary ease with which a distinct breed can be produced from a spontaneously appearing variety. In spite of all the swamping effect of continual and uninterrupted crossing with the normal form, I have never been able to record a normal family, while in many cases some of the kittens were equal to, or even beyond, the abnormal parent in her peculiarity. This being the case, it is clear that a breed would have been quickly established if abnormal males had been selected to pair with the abnormal females. These observations have, therefore, an interesting bearing upon the existence of such a local breed as the tailless Manx cats, as Prof. E. Ray Lankester pointed out to me when talking over the subject. Prof. Lankester supposes that a tailless individual appeared spontaneously, and that it was considered interesting and a curiosity; and when the abnormality re-appeared in some of the offspring, these were kept in preference to the normal forms. It seems quite certain that the result might have been produced in this way, and I have arranged with Dr. Grabham, of Madeira, that some of my abnormal kittens shall be sent to him to turn loose upon some neighbouring Atlantic rock on which rabbits are the only other living mammals. I should add that Prof. Lankester found a support for the theory of the origin of the Manx breed of cats in the fact that there are tailless breeds of other animals which are also fashionable in the locality, and which seem to point to the existence of the same peculiarities of taste working upon a spontaneous variety. In fact, as Prof. Lankester suggested, the people may have rather looked out for other tailless or abnormally short-tailed animals, when their interest had been excited by the existence of one such breed. But the observations here recorded have also a bearing upon those cases in which natural, instead of artificial, selection has been the agent. Granting, as I believe we must do, that some adaptive characters of great importance owe their beginning to flashes of structural or functional originality—appearing suddenly and spontaneously in one individual, as the extra digits appeared in the ancestor of my cats,—we see from these observations that in spite of all the effects of constant intercrossing with normal forms, there would be a most persistent offer of material upon which natural selection might work, for the variation would appear to a greater or less extent in a very large proportion of the individuals of the various families produced, while again and again the peculiarity would be inherited in a form equal to or even beyond that of the parent. It is therefore of interest to actually test a few instances in as complete a manner as possible, taking care that only one parent possesses the abnormality, for this is what must have happened for the first few generations of any such variety which originally appeared in a single individual in a natural state. It is chiefly with the object of adding another to the instances already known and worked out that these observations have been undertaken, and will be continued and rendered as complete as possible. It need scarcely be pointed out that such instances differ essentially from all the cases in which breeds of domestic animals have been established, for in these well-known and numerous breeds heredity has had undisturbed possession of the field, without any confliction between the normal and abnormal forms, except indeed in the case of the first family produced by the original parent of certain breeds of which the peculiarity appeared spontaneously in a single individual, as in the breed of "otter" sheep.

EDWARD B. POULTON

LIGHTHOUSE ILLUMINANTS[1]

THE details of the construction of the three towers and lanterns, and of the lenses and lamps in each lantern, of the magneto-electric machines, and of the gas-works, have no doubt been placed on record, and will be reported by the Trinity House engineers. But the following may serve as a general description of the arrangements.

Three low towers, constructed of massive timber, have been erected in a line inland from the higher of the two permanent lighthouses on the South Foreland, the nearest being 245 feet distant from the lighthouse, and the three being separated one from another by intervals of 180 feet. Their height, varying with the level of the ground, so that the lanterns may be on the same level, is from 20 to 30 feet; upon these structures rest three similar lanterns about 20 feet in height and 14 feet across. Within the lanterns are columns of lenses forming two opposite sides of a hexagonal framework which rises from the base to near the top of each lantern. The whole framework can be made to revolve so that either column of lenses may be made to face in any direction; each column consists of three or four similar lenses superposed, but the lenses forming different columns are different in their purpose and structure, and in their size. One column in each lantern consists of lenses designed to gather the divergent rays which fall upon them from the central source of light into a level sheet which spreads over the surface of sea or land, but not downwards or upwards; each of these lenses is a segment of a cylinder, and may be described as a cylindrical lens. The opposite column in the gas and oil lanterns consists of lenses designed to gather the divergent rays, not into a sheet, but into a single cluster or cone of small vertical angle, which is sent forth horizontally in any one direction. These lenses are made up of a central circular lens, surrounded by annular prisms and segments of such prisms, the whole fitting into a rectangular frame; they may be called annular lenses. The corresponding column of lenses used with the electric light consists of cylindrical lenses with condensing prisms placed in front of them; the cylindrical lens flattens a broad cone of light into a fan, the condensing prisms close the fan.

The size of the cylindrical lenses placed in front of the gas and oil lamps is the same, but the lenses in front of the superposed electric lights are smaller. The annular lenses, of which three form a column in the oil lantern, are each 6 feet 3 inches in height, while the four superposed annular lenses in the gas lantern are each 3 feet 9 inches in height. Both sets of annular lenses have the same width, namely, 3 feet 5 inches.

The electric lights are large arc lights, supplied with the electric current by three magneto-electric machines, which are worked by the steam-engine in the engine-house built for the ordinary work of the station. The electrical apparatus is of the construction of Baron de Méritens.

The gas-burners tried hitherto are of Mr. Wigham's construction, consisting each of a multitude of small fish-tail jets on brass stems about 6 inches long and an inch one from another, arranged on the same level in concentric rings. A tall funnel, a few inches above the cluster of burners, draws their flames together into the form of a bell. The number of concentric rings may be changed quickly so as to increase or reduce the size of

[1] Preliminary Report of Mr. Vernon Harcourt to the Board of Trade on the Experimental Lights exhibited at the South Foreland.

the burner from a diameter of about 4 inches with 28 jets, to a maximum of 11 inches diameter and 108 jets.

The oil lamps are of the usual Trinity House pattern with six concentric wicks, and are fed with paraffin oil.

Cannel gas is manufactured and stored at a short distance from the experimental towers, and supplied through a meter to the gas-burners.

For the observation of the lights, which were first shown in the week beginning March 30, three huts have been erected at different distances along a line perpendicular to the line of the towers, and this line has been marked by posts showing the distance from the central tower. The lighthouse-keepers who are stationed in one or other of these huts are instructed to make hourly observations during the time the lights are exhibited, expressing in figures their estimate of the relative brightness of the three lights. When the night is misty the keepers are instructed to patrol the line of posts, and to record the distance at which each light is lost or becomes visible. To avoid prejudice in favour of either an old or a new mode of lighting, the towers have been labelled, and are called A (electricity), B (gas), and C (oil). The huts are numbered. No. 1 is rather more than 700 yards distant from the central tower, No. 2, about $1\frac{1}{6}$ mile, and No. 3, $2\frac{1}{2}$ miles. Steps have also been taken to obtain estimates of the relative brightness of the three lights from observers at greater distances. To secure the identification in each hut of the lights observed when all three are not visible, three tubes have been fixed in each hut directed towards the lights A, B, and C, and labelled accordingly.

The huts serve also for measurements by various photometric methods of the light sent forth from each lantern. A number of such measurements have already been made, the results of which have been communicated to the Board of Trade by the Trinity House.

Near the engine-house on the South Foreland a long gallery has been built, in which the light emitted by the various lamps employed or proposed to be employed, can be measured so as to ascertain the value of these lamps independently of the lenses by which, within the lighthouse lanterns, their apparent brightness is variously augmented.

The experimental inquiry thus instituted will serve :—

(1) To ascertain the amount of light given by the six-wick and seven-wick oil-lamps, and of other oil-lamps, or modifications of them (if any) which may be proposed for lighthouse service.

(2) To ascertain similarly the amount of light given by Wigham's gas-burners on different scales (28, 48, 68, &c.) with different rates of consumption, and, if thought well, with different qualities of gas, and to test other gas-burners in like manner.

(3) To furnish further and trustworthy measurements of the light given by the electric arc with various carbons and with various tensions and quantities of electricity, and to test the efficiency of the De Méritens magneto-electric machines in converting mechanical into electrical energy, and whether they work without difficulty or risk of break-down or need of repair or loss of power; also to test the working of the De Méritens electric lamp, and of other electric lamps, if thought well.

(4) To furnish additional data for estimating the cost of maintaining any given light for a certain time, say 1000 candles for one hour, by each mode of producing light, and on the various scales suitable to different localities.

(5) To measure the efficiency of the lenses employed, especially with flames of different sizes in their foci.

(6) To prove experimentally (if such proof be desired) that 2 or 3 or *n* similar lights, when juxtaposed, give twice or thrice or *n* times as much light as a single light gives.

(7) To ascertain what light is sufficient to be visible from its horizon on a clear night, and in what ratio on the average of many nights the visibility of a light at great distances increases with its total intensity, or lens area, or proportion of red or of blue rays.

(8) To test the effect of the variations last named in haze, or mist, or fog, or rain, or snow, that is, when the air is made more or less opaque by particles of liquid or solid water of various sizes suspended in or falling through it. Such testing may be made either photometrically, which is only possible in slight haze and at small distances, or by observations of the distance at which each light is lost or reappears.

(9) To try the question of the utility of ex-focal light, whether, that is, it often happens that the position of a lighthouse may be seen by the illumination of cloud or fog above or around it, when its position would be unknown if equal light from a smaller focus were directed almost wholly towards the mariner, and not allowed to spread.

(10) To test further whether in mist or haze sudden flashes of a powerful beam of light are noticeable when an equal light maintained constantly, or waxing and waning gradually, would not be noticed.

It is likely that other subjects of experimental inquiry may be suggested by those experienced in lighthouse illumination, or may occur as the experiments proceed. But, taking those above enumerated in order, I will attempt to indicate the conclusions which at present appear probable, and to make some suggestions as to points still to be investigated.

(1) It appears that the six-wick oil lamp behind the annular lens sheds light of as great intensity as the seven-wick lamp, while its consumption of oil is much smaller. Probably this result is due, in part, to the fact that the outer ring of flame which the seventh wick adds is further from the focus of the lens, while each ring of flame is partially opaque to the light from the rings inside it; and partly to the fact that the seven-wick lamp has not yet been brought to so perfect an adjustment of oil-supply to air-supply as the six-wick lamp.

I do not know whether any oil-lamp used in other than English lighthouses is such as to merit a trial against the Trinity House lamp.

(2) Some observations have been made with Mr. Wigham's burners with 88 and with 108 jets, which seem to show that with gas as with oil, behind the annular lens, no gain in intensity of light results from the circaposition of another ring of flame. Some evenings should, I think, be devoted to trying this question out. The value of ex-focal light behind an annular lens seems to be almost *nil* as regards intensity, and, if so, it may be well to use with revolving light a smaller flame than that of the six-wick lamp. Excellent experiments on this question can be made with Mr. Wigham's burner by exhibiting on a clear night through the annular lens one of these burners, whose size should be reduced, after an interval sufficient for photometry, from 108 jets to 88, and so on to the smallest size, measuring also after each change the consumption of gas. It will probably be found that a large fraction of the *directed* light is still obtained with a relatively small consumption of gas, and with the accompanying advantage of a low temperature within the lantern.

Similar measurements should be made with a cylindrical lens and with the naked flame in the photometric shed.

At present one other gas-burner besides Mr. Wigham's has been tried, a ten-ring gas-burner devised by Sir J. Douglass, which has given an excellent yield of light. Two others, by W. Sugg and Co., and by the F. Siemens Company, await a trial. The problem which the maker has to solve is to pack as much highly luminous flame as possible into a sphere of 3 or 4 inches diameter.

Where gas has to be manufactured expressly for a lighthouse, it would generally be best to make cannel gas, but near a town where common gas could easily be laid on, it would be cheaper to use common gas. It might, therefore, be worth while during the course of the experiments to charge the small gas-holder with common gas, and to note the consumption and the light developed. It would probably be found that with suitable burners the chief disadvantage in using common gas was the greater development of heat, the same light being obtained from the consumption of a larger volume of lower priced gas.

(3) Many measurements have been made in recent years of the light of the electric arc, but the difficulty of making measurements of so variable a light, and the uncertainty attaching to the standards of light employed, and the great differences between one arc light and another, according to the electric current and the carbons employed, make it clearly desirable to have further measurements of the electric light at the South Foreland.

Photometry should be accompanied, as with oil and gas, by a measurement of consumption. The mechanical energy absorbed can be measured at the strap which connects the magneto-electric machine with the steam-engine. The electrical energy developed can be measured in tension maintained, and quantity used, at the leads connecting the machine with lantern A. The cost of each horse-power per hour on the actual scale of working at the South Foreland must be already known. The rate at which the two forms of carbons which have been tried are consumed is also known.

It is essential to the value and significance of the photometry that simultaneous electrical measurements should be made.

The possible variations in the coupling of the magneto-electric machines, in the rate of running, and in the nature, form, and adjustment of the carbons, present a wide field of experimenting.

The continuance of the experimental working for many months will serve for a trial of the trustworthiness of the De Mériten's apparatus for lighthouse service.

(4) The cost of maintaining a lighthouse supplied with gas has been very variously estimated. It must vary from place to place, especially with the price of coal. The actual working expenses of oil lighthouses on the English coast, and gas lighthouses on the Irish coast, with allowance for the price of coal and labour, should furnish trustworthy data for a comparison. But to complete these data the quantity of light produced and utilised in each case needs also to be known, and as both the oil and gas burners tried hitherto at the South Foreland are of the service kind, the photometry now in progress will supply this knowledge. Some information may also be gathered from the expenditure on each illuminant at the outset and during the course of the experiment. It should be possible to state, if it were desired to maintain on the South Foreland a light of 50 or 100 or 200 thousand candles, what its annual cost cost would be with each illuminant.

(5) Although the action of lenses is mainly calculable, and, so far, does not require trial, it is modified by two quantities which vary slightly, namely, the reflection and absorption of light by glass, and is affected to some extent by errors of workmanship. It will, therefore, be of interest to obtain an exact comparison between the light emitted by a naked flame, and that from the same flame concentrated by different types of lighthouse lens. The prediction of the effect of a lens is less possible when the illuminant is of large size; and the failure of lenses, constructed for use as a revolving light with gas, to utilise (except by broadening the beam) the light produced at a distance of more than two or three inches from the focus of the lens, if they are found to fail so far, may be worth demonstrating.

With the electric light a very close correspondence should be found between the calculated effect of the cylindrical lens and of the condensing prisms and the results of photometry.

(6) The measurements which have been made of multiform gas and oil may be taken to show that any number of lights at a given distance cause so many times the illumination which one light causes; or assuming that the above must be the case, and is involved in the conception of comparative illumination, the proportional variation of the photometric results with the changes from uniform to biform, &c., on clear nights, gives evidence of the trustworthiness of the photometric methods.

(7 and 8) The two questions, which I have numbered thus, can hardly be treated separately, since clearness differs only in degree from slight haze, and slight haze from fog. Together they constitute the chief object of this inquiry.

The observations of the experimental lights which have been made from a distance, may be expected to yield, when they are collected and compared, much information as to the distances at which the several lights have been seen in various weather. But the changes which are necessary when photometric testings are to be made, or when an extensive programme is to be exhibited, must to some extent have interfered with the observation of the changes due to variations in the transparency of the atmosphere. It might be well for at least one month, to show the same lights nightly, and to inform the distant observers that this was about to be done, in order that their observations might have the more value. A single light of each kind shown through the cylindrical lenses would serve as well as multiform lights, and it would be best to use that size of gas-burner which had through the lens equal illuminating power with the six-wick oil lamp. Unless, indeed, it is assumed, as I should be inclined to assume, that equal lights from gas and oil have the same power of penetrating haze; in which case it would be more instructive to show from tower A a single electric light supplied from one machine, and from B and C either gas or oil also single, and either oil or gas of such size and number as to have at close quarters on a clear night an illuminating power equal to that of the electric light. A sufficient series of distant observations of these lights would show (1) whether the electric light maintained its equality with the larger hydrocarbon flame through slight haze, or became more nearly equal to a flame of much less initial brightness; and (2) whether the taller beam of multiform oil or gas had much advantage over the beam sent forth from a single lens. I believe it will be found that the relative brightness of two, or more, to one, will be maintained at any distance and through any haze which permits of photometry, but that, when the single light is lost at 5 miles or 500 yards, the triple light will be invisible at 6. The actual figures corresponding to these conjectural figures must be found, and the Trinity House Committee will then be able to judge in what cases such an extension of range is worth the increased expenditure.

In the case of the electric light, the observations which have already been made show that it loses in haze a larger proportion than the hydrocarbon flames. Further observations on this point will be of much interest and importance. The most valuable are observations of the distances at which an electric and a gas or oil light, whose relation in clear weather is known, cease to be visible. Such observations are strictly photometric observations, in which the lights observed are brought to an equality of minimum appreciable brightness, and the distances at which their brightness is equal are measured. These are dependent upon the weather, and may be practicable on only a few days in each month. Still more rarely will the opportunity offer of measuring the lights in hut No. 1 through a slight uniform mist; but such measurements ought to be made. I would suggest the possibility of testing in the photometric shed through an artificial mist produced by blowing steam from the boiler in the adjoining engine-house into the middle of the shed.

It is said that Faraday proposed at first the use of a very small lens with the electric light. Unless conclusive experiments have been made on this point, it may be well to place the experimental electric light in the focus of a larger and of a smaller annular lens, each subtending the same angle, and to note whether the effect differs.

It might also be worth trying whether biform gas, with a small enough number of jets to have the same illuminating power as single oil, would be better seen through slight haze. The trial would not be between gas and oil, but between placing a strong light behind one lens, and placing half the light behind each of two superposed lenses.

(9) Owing to the nearness of the three lanterns, the illumination or halo which spreads round each of them in a fog seems almost to blend. That which surrounds the gas lantern is not much greater than that around its neighbours on either side. I do not think that, on the one occasion on which I have seen the lights in a fog, the ex-focal light was of much service.

If a lighthouse lantern was surrounded by a mist or cloud extending far enough laterally to extinguish its principal beam, but so little above it as to allow the scattered light to fall upon a higher stratum of cloud, the position of the lighthouse might only be seen from the illumination of the cloud above it. But this state of things would happen rarely in most places, and a better plan of turning it to account than the addition to a burner of rings of ex-focal flame would be to employ the upper prisms to send a second beam skyward. Whether the general illumination about the experimental lanterns has been visible when the three centres of light were not visible to an observer towards whom the beams were directed, may perhaps be gathered from the record of observations.

(10) When engaged on a clear night in judging of the experimental lights, the eye of the observer is continually caught by the sudden flashes of the Calais light. The revolving light at Grisnez is equally visible, but does not catch the eye in the same manner. It might be well to try on some rather hazy night, whether, if one lantern alone were lighted, and during successive quarters of an hour the light were alternately kept steady and flashed in some such groups of flashes as the Calais light, the observers patrolling the line of posts became aware of the light at a greater distance when it was flashed than when it was steady or revolving. Even a slight mist is a great leveller of distinctions, but it seems possible that the use of flashing may increase the range of a light as much as an addition to its intensity or size.

Some of the questions raised in the latter part of this report might perhaps have been omitted, as having already received an answer, if, while thinking the matter over, I had been able to consult some of the experienced members of the Trinity House Committee who are charged with the conduct of this inquiry. I have ventured here in writing, as at other times by word of mouth, to make the suggestions which have occurred to me, knowing that they will receive friendly attention if they are submitted to the Committee, and hoping that some of them may be of service. (Signed)

July 26, 1884 A. VERNON HARCOURT

Since[1] the foregoing preliminary report was presented to the Board of Trade, the experimental inquiry has come to an end, and a complete account of the apparatus, observations, and testings has been published by the Committee of the Trinity House who had charge of the inquiry, followed by a statement of the conclusions at which the Committee have arrived.

I propose to arrange the remarks I have to offer under the following heads:—

I.—Apparatus for the exhibition of the experimental lights.
II.—Arrangements for observation.
III.—Photometry.
IV.—Comparison of lights.
V.—Range of lights in hazy weather.
VI.—Cost of each system.

I.—*Apparatus for the Exhibition of Experimental Lights*

In my preliminary report I have given a general description of the temporary towers, the lenses and lamps. In Parts I. and II. of the Trinity House Report are to be found plans and measurements giving the full details of these constructions. The towers are admirably suited to their purpose, and their situation and the distance between them proved most convenient for observation.

In regard to the arrangements for exhibiting the electric light, it is to be observed that, although the electric light completely outshone its competitors, it was heavily handicapped in the competition. The "leads" were not of sufficient calibre to carry the large electrical currents used, for a distance of nearly 300 yards, without considerable loss. Prof. Adams estimates the loss at more than one-fourth the electrical energy supplied.

The five vertical prisms used in the case of the electric arc to bring together the horizontal rays, subtended an angle of only 30°, while the annular lenses which served the same purpose in the gas and oil lanterns subtended an angle of 60°. Thus the fraction of the light emitted from the central source of light, which composed the revolving beam, was only half as great in the case of the electric arc, as in the case of the gas and oil flames. It seems probable also that a beam of less divergence may be used with advantage to obtain a maximum range in hazy weather; and such a beam may be obtained from the electric arc with lenses of moderate size. On a few occasions when an annular lens similar to those used in the other two lanterns was placed in front of the electric arc, the light was dazzling at a distance of more than a mile, and surprisingly vivid at a distance of 20 miles. I see that on a clear night when the 108-jet gas burner behind an annular lens gave a light of 60,000 candles, the electric arc behind its cylindrical lens and vertical prisms gave a light of 1,200,000 candles, and behind an annular lens a light of 12,000,000 candles. In the one case the arc was five times as powerful as Mr. Wigham's "quadriform," in the other fifty times as powerful.

For the sake of uniformity and comparison under similar conditions, only the central belt of the Fresnel apparatus was placed round the electric lamp as round the gas and oil burners. The suppression of the top and bottom prisms, though entailing a loss of 30 per cent. of the light produced, is a necessary sacrifice where large burners developing great heat are placed immediately one over the other. But each of the electric lamps in tower A might have been surrounded with a complete Fresnel apparatus, adding nearly one-third to their light, without any difficulty or any necessity for separating them more widely.

Thus, if the principle which has been enunciated had been followed, of doing for each illuminant the best that could be done within the limits of the lighthouse lantern, if a triform electric light had been exhibited, with leads of low resistance, with a lens subtending an angle of 60°, and with top and bottom prisms, the power of this light might have been more than tripled. By also reducing the divergence of the beam, which I think might be done with advantage, a further increase of power could have been gained. This fact should be borne in mind in comparing the results which were obtained with the three illuminants.

[1] Further Report of Mr. Vernon Harcourt to the Board of Trade on the Experimental Lights exhibited at the South Foreland.

In M. Allard's interesting and important "Mémoire sur les Phares électriques," 1880, he gives the results of a trial of three Gramme dynamo-machines and an electro-magnetic machine of the Alliance Company. The former gave for the same horse-power 40 or 45 per cent. more light than the latter. But M. Allard measured only horse-power and light, not the electrical energy developed; and it does not appear whether the larger yield of light was due to a more powerful electrical current, or to the position of the carbons, and the form of the incandescent ends, being more favourable to the emission of light with the continuous current. Probably the De Méritens machines, which produced a light of about 1000 candles per horse-power, are superior to those of the Alliance Company, which yielded only 540 candles, and are equal to the Gramme machines which yielded 800 candles per horse-power. Of all that relates to the economical production of powerful arc lights, knowledge is advancing rapidly. The ample provision of steam power, and the excellent photometric gallery at the South Foreland, will no doubt be used from time to time for the trial of new types of electrical machines, of regulators, and of carbons. For the past experiment, and apart from the question of cost, the De Méritens machines worked admirably, converting, according to the measurements of Prof. Adams, mechanical into electrical energy with a loss of only 16 per cent. The current supplied was more than sufficient for the largest carbons; indeed, carbons exceeding 1½ inches in diameter were heated to redness through their entire length.

In regard to the apparatus for exhibiting the gas system of Mr. Wigham and the oil lamps of the Trinity House, little can be added to the full and clear account of the Trinity House Committee. But as it has been stated, since the publication of the Trinity House Report, that Mr. Wigham's foreman was not left unfettered to make the best display which the apparatus in his charge would allow, I may here put on record what I saw and believe in the matter. I paid many visits to the gas lighthouse by day and by night, and was in frequent communication with the foreman, Mr. Higginbotham, from the beginning to the close of the experiments. The arrangement of each night's programme rested with the Committee of the Trinity House, who so ordered matters that abundant opportunity was given for the observation and measurement of all the varieties of each illuminant. Among these were Mr. Wigham's combinations of 28 jets, 48 jets, 68 jets, 88 jets, and 108 jets, the ready conversion of one of which into another is among the merits of his ingeniously constructed burner. When the effect of the smaller number of jets was to be observed, it is clear that the full power of the burner could not also be shown. Therefore, there were necessarily times when Mr. Wigham's foreman was not free to make the best display which the apparatus in his charge would allow. With this exception only, I believe that Mr. Wigham's foreman was perfectly free to do his best and make any improvements Mr. Wigham or he could devise. I see from the summary in the Trinity House Report that the full power of Mr. Wigham's burners was shown on 127 nights; and it appears from the photometric record that it was measured 57 times. This ought to suffice for an accurate judgment of its merits.

Comparing the gas and oil towers as they appeared to a visitor when in full operation, the gas had one striking advantage, and one equally obvious disadvantage. The advantage was that it needed no care. When the lenses had not to be revolved by hand, nor the number of jets changed, one attendant in the tower was sufficient, and he had little or nothing to do. In the oil tower, on the other hand, I have seen a keeper on every one of the three stages, each man watching and from time to time adjusting his lamp. The disadvantage encountered in the gas tower was the excessive heat from the large gas-burners, which by causing unequal expansion of the glass lenses and their metal framing, and of the outer and inner surfaces of the lenses themselves, caused cracks to appear, which in the continuous belt of thick glass gradually spread from side to side. But though the burning of gas yields for the same light more heat than the burning of oil, there is no reason to think that with a diminished consumption of gas, *e.g.* the 160 cubic feet an hour of the 68 jets instead of the 300 of the 108 jets, such a disaster would recur. When the gas flame is surrounded by a chimney, as in Sir James Douglass's and Mr. Sugg's multiple Argands, the heating of the lenses is greatly diminished.

When the lights were first exhibited, the behaviour of the oil lamps in C tower was a matter of much interest. Using gas, Mr. Wigham had succeeded in quadrupling the power of a large burner behind a lens more than a yard square, by placing over it three other similar burners and lenses. But it seemed a hazardous experiment to imitate this plan by placing three lamps fed with mineral oil one over the other. However, the skilful arrangements of Sir James Douglass were completely successful. The three superposed oil lamps burnt as safely and well as if each had had the lantern to itself.

II.—*Arrangements for Observation*

A short account of these arrangements have been given in my previous report, and a complete account is to be found in the report of the Trinity House Committee.

The plans for making observations on shore at small distances had been well laid. The home at St. Margaret's, stationed between the two observing huts, with telephone to all points; the measured distances; the huts themselves, welcome refuges on a cold night, and most convenient for photometry with their helpful occupants; all bore witness to the wise forethought which had been bestowed upon the details of the inquiry.

For obtaining records of the relative brightness of the different lights from the impressions of those who saw them, probably no better plan could have been devised than that of distributing forms to be filled in with a numerical estimate of the ratio which two of the lights bore to the third. And the enlisting a multitude of observers, by the wide distribution of these forms, secured the two advantages, of an average drawn from a very large number of observations, and of an obviously impartial judgment. The observations made at sea from the Trinity House yacht *Argus*, which was in constant attendance, were of great importance; and I may add that, for the landsmen whose main business was photometry at small distances on shore, taking part in these observations was an essential help towards the full appreciation of the problem before them.

III.—*Photometry*

The chief assistance which I found myself able to render to the Committee was in devising and improving photometric apparatus and methods. A full description of these is given in the Committee's Report, especially in Mr. Dixon's "Record," part ii., pp. 30–36. During my visits to the South Foreland, I was principally occupied with photometry, in the dark gallery by day, and in one of the huts by night. Frequently Mr. Longford or Mr. Dixon worked with me, and the observations which I made are included in the general record. I believe that the standard of light employed was constant and of a definite and reproducible value, and that the methods of comparison were trustworthy and accurate. The excellent idea of Sir James Douglass, of using a large lens to concentrate the rays from the lighthouses upon the photometric disk, made possible the measurement in the more distant hut of lights whose intensity was too feeble to be accurately estimated without such aid. Mr. Dixon's polariscope photometer and the ingenious obscuration photometer of Captain Nisbet, are instruments well adapted for the direct comparison of distant lights or lights enfeebled by haze; the former can only be used for lights which are near together. Two movable photometer-bars, designed by Sir James Douglass, and suitable for use with any form of disk and any standard, were in constant employment throughout the trial. These were placed in the photometric gallery and in hut II. The observations in hut I. were reduced by means of a portable bar devised and made by Mr. Dixon.

A glance at the 16 columns of the closely-printed photometric record,—each number being, as a rule, the average of many observations,—will give to those who know the effort of attention which accurate photometry requires a conception of the diligence with which this branch of the inquiry was pursued. I have spent many hours in one or other of the huts with Mr. Dixon or Mr. Longford, and I wish to express my conviction that the results which they obtained and which are printed in the Trinity House Report, are as complete and trustworthy as zealous, patient, and skilful work could make them.

IV.—*Comparison of Lights*

Although an observer's opinion on the relative brightness of two or more lights, like an opinion on the force of the wind, is better expressed by means of numbers than by descriptive terms, such numbers must not be regarded as expressing the relative intensity of the lights so compared. Perhaps on any future occasion it would be better to call the brightest light 10 rather than 100, since the use of the larger number suggests that an inferiority just sufficient to be noted with confidence is to be expressed by a difference of 2 or 3 per cent., whereas it probably amounts to at least 10 per cent., and 9/10 or 8/10 would be nearer the ratio of the two lights than 98/100 or 95/100. No doubt by practice in comparing lights whose relative intensity is known, a fair power of judging may be acquired; but without such training the natural tendency is to under-estimate differences. For example, the average of 294 estimates by eye of the relative power of "triform oil" and "quadriform gas," assigns to the gas a superiority of 6 per cent., whereas the actual superiority as shown by measurement is 23 per cent. According to the same series of estimates the electric light has a superiority over "quadriform gas" of 59 per cent., the actual superiority being more than 400 per cent.

Equally remarkable evidence of the tendency to overlook differences of intensity when the estimate is made directly by eye, is found on comparing the values assigned to "multiform" lights. The figures relating to the 108-jet gas-burners, and representing the relative value of the single, biform, triform, and quadriform lights, each by comparison with the electric light, are 56, 61, 59, and 63. If these numbers represented the intensity of the light falling upon the eye from the whole surface of the illuminated lenses, they should stand in the ratio of 1, 2, 3, and 4. The explanation at once suggests itself that while the photometer measures the total light received from a large illuminated surface, the eye judges of the brightness of the surface or the light received from equal areas. To an observer looking down a street on a clear night, the more distant gas-lights seem as bright as those which are nearer, though smaller in size; if asked to estimate the lights he would probably assign the same figure to all. And the visual angle subtended by the flame of a street-lamp at 100 yards is about the same as that subtended by 18 feet of lenses at a distance of 4 miles. The singular fact that as estimated by eye, on a separate comparison with the electric light, "multiform" have no superiority to single lights, may to a small extent admit of the explanation which applies to the familiar case which has been given. In this case the observer distinguishes between size and brightness, and sets himself to judge of the latter only; or it may be that the intensity of the sensation of light depends upon the brightness and not the size of the spot of light formed upon the retina. But the South Foreland observations were not made chiefly at distances of only 2 or 3 miles; nor were the observers likely to disregard the apparent magnitude of a light in estimating its value. At distances of from 12 to 14 miles, at which the largest lights have no appreciable magnitude, the average values assigned to the biform, triform, and quadriform lights are 75, 66, and 60.

I fear the true explanation is that the results have suffered from the electric light having been adopted as the term of comparison. To a small extent its fluctuations and difference of colour, and to a much greater extent its incomparable power, have made the estimates entirely uncertain; and thus it is vain to institute cross comparisons between the different lights which were not seen together, but only estimated by reference to the electric light as a standard. This conclusion, however, does not affect the value of the comparisons, chiefly aimed at, between the gas and oil lights, which were seen together, nor the significance of the direct comparison of the flame lights with the electric light at all distances and in all weathers. Indeed, the adoption of the electric light as the standard with which all others were to be compared, has served to establish on the basis of thousands of observations the important fact that, as far as the eye can judge, the electric light appears to excel the light of gas or oil lamps almost as much at greater as at smaller distances, and in hazy weather as in clear. The mean ratio of the electric light to all the gas and oil lights exhibited, taken from the whole number of recorded observations, is, at distances of from 1 to 8 miles 1000/626, at distances of from 8 to 15 miles 1000/613. In clear weather the mean ratio is 1000/591; in weather not clear it is 1000/608.

The photometric record presents many points of interest.

In the measurement of naked flames the long gallery, which has wisely been made a permanent structure at the South Foreland, afforded unexampled facilities. The electric arc was measured at a distance sufficiently great for its intensity to be similar to that of the other lights which were measured. The values assigned to it, from 10,000 to 15,000 candles, are not so high as some which have been obtained; but this is perhaps due to the fact that extreme values were rejected, and care was taken to obtain an average result.

In one respect the observations are incomplete, and need to be supplemented at some future time. Within the lighthouse the source of light is surrounded by an apparatus which gathers together the light sent forth in all directions, excepting a small angle above and below. Thus, the intensity of the light sent in a sloping direction upwards and downwards is of as great importance as that of the light sent forth in the horizontal plane. But only the latter has hitherto been measured in the photometric gallery. According to M. Allard the electric arc produced by an alternate current sends out horizontally an amount of light which is 11 per cent. greater than the average amount sent in all directions. With a continuous current the strongest light is thrown on the side opposite to the positive carbon; but it happens that with an arc light of this description horizontal measurement gives the average value. Probably Mr. Wigham's wide cluster of gas jets sends forth less light horizontally, owing to the imperfect transparency of one flame to the light of another, than it sends in an upward direction; and the same may be the case with the concentric gas-burners and oil lamps. Mirrors might hereafter be arranged within the photometric gallery, which would serve for making these measurements.

To determine accurately at a distance the power of the various lights exhibited was an essential preliminary to calculating the range of any of the lights in hazy weather. And although this power is approximately calculable, the power and dimensions of each flame, and the structure of each lens being known, it was of great interest to make actual measurements of the intensity of the light at two different points, and in different states of the atmosphere. I am not aware that such measurements had ever before been attempted. Owing to the novelty of the photometric problem, and to some extent of the methods employed, it was highly important to have some means of testing how far the results were trustworthy. Such means were furnished by the multiform system of Mr. Wigham. At any distance, and in any state of the atmosphere, the illumination produced by a combination of two or more similar lamps and lenses is so many times as great as the illumination produced by a single lamp and lens of the same kind. Thus, among the lights to be measured were several whose relative power was known beforehand. If testings of single and multiform lights, made in succession while the degree of clearness of the air was unchanged, gave values varying approximately as the number of lights, an equal degree of exactness may be ascribed to the testings of other lights and lenses.

On July 12, the weather being "clear, calm, overcast," the light from the single, biform, triform, and quadriform 108-jet burners, showing through Mew Island lenses, was measured at hut I. The results in thousands of candles were 50, 98, 168, and 214. Three testings intervened between the second and third, and probably the air had become a little clearer, but the numbers are not far from the ratio 1, 2, 3, 4. Three days later the same single, triform, and quadriform combinations were tested one after the other, also at hut I. The values found are 48, 145, and 186. Similar testings were made on July 23, on a clearer night, of all four combinations; their power was found to be 58, 112, 171, and 220 thousands of candles. Probable values in the ratio of 1, 2, 3, 4, are 56, 112, 168, and 224. On the same night the value found for a single six-wick oil lamp behind an Eddystone lens was 56,000 candles, and for three such lamps behind three such lenses 168,000 candles. On November 1, in thick haze, the value found at the nearer hut for "I. Gas, 108, M.," was 25,500 candles, and for "IV. Gas, 108, M.," 102,000. The results obtained at hut II., with a wholly different photometer, are confirmed in the same manner. For example, on February 7, consecutive testings on a misty night of "single" and "quadriform gas" gave in thousands of candles the numbers 26 and 101. On March 20, on a very clear night, the values found for the same two lights were 63 and 252.

In looking over the tables of the photometric record, and comparing the figures standing against combinations of equal numbers of oil lamps behind Eddystone lenses, and of the larger gas-burners behind Mew Island lenses, in all weathers in which the lights were measurable, the eye is struck by the similarity of the numbers. The rival systems are nearly equal; there is little to choose between them. Still less difference, as has been pointed out, was discernible on looking, as we did night after night, at the lights themselves. Other considerations than that of visibility in either clear or hazy whether, must decide which, if either, of the two systems is to be generally adopted for lighting our coasts. By multiplying burners and lenses, and by enlarging the size of the lenses, more powerful lights still may be produced, if it is thought desirable, with either illuminant.

But the most prominent fact on the face of the photometric record is the immense superiority of the electric light. The conclusion forces itself upon the reader of these tables that if greater power is needed, it is to be found, not by magnifying lenses or multiplying combinations of gas or oil burners, but by substituting the light of the electric arc.

The Trinity House Committee report that the electric light in clear weather is certainly not popular with sailors, chiefly on account of its dazzling effect at short ranges. But at ranges exceeding two or three miles, "hyper-radiant," or even multiform lenses, are not visibly larger than such a lens as is suitable to the electric arc; and at such ranges the "dazzling effect" is simply that due to the power of the light. If a double quadriform were as powerful it would dazzle as much. Also the use of a powerful electric arc in clear weather may be avoided. It would not be difficult to arrange for the use of a small electric arc during clear weather, and the quick substitution of a powerful arc light when the weather became hazy. I would venture to suggest that the singular circumstance which led or contributed to the removal of the electric light at Dungeness, that a vessel went ashore near the lighthouse, may have been due, not to the dazzling effect of the light, but rather to the diminution of brightness as the approaching vessel passed within and beneath the range of the light. With the condensed and sharply-defined beam of the electric light, it may perhaps be desirable to devote some part of the optical apparatus to spreading a portion of the light over the space intervening between the coast and the point, a mile or two away, at which the principal beam first strikes the sea. If this is done, the light at short ranges might be made sufficient, but not too dazzling; and for longer ranges there seems to be no reason why the powerful beam produced by the electric arc behind one of the Mew Island lenses should not be employed. This beam had a divergence of about 1°. Even from the high level of the South Foreland lights, if the axis of such a beam were so inclined that only about $\frac{1}{6}$ of the light passed over the horizon, the full light would extend to within about three miles of the shore. Since the apparent brightness of every light must vary with the state of the atmosphere, as well as with the distance of the light, and as the angle subtended, even by a multiform light, at a few miles distance is very small, it cannot be possible by the appearance of a light without other data to judge of its distance. The electric light is not singular in this respect.

(To be continued.)

THE LUMBAR CURVE IN MAN AND APES

We are indebted to Prof. Cunningham, of Trinity College, Dublin, for a well-illustrated and exhaustive memoir on the subject of the lumbar curve in man and apes. This memoir has been printed by the Royal Irish Academy as one of the Cunningham Memoirs, and is illustrated by thirteen plates, several of which are large folding ones, and two of which are large coloured drawings of the two surfaces of a mesial section of a male chimpanzee; these are life-size, and are the first accurate representations of the topographical anatomy of this anthropomorphic ape we have seen.

The structural differences between man and the anthropoid apes are no doubt in a great measure due to the assumption by man of an erect attitude, and to his having from an early period of his life dispensed with the use of his anterior extremities as organs of locomotion. The vertebral column of man might be expected to exhibit in a marked degree differences distinguishing it from other animals, and that more or less deep convexity forwards in the region of the loins has been considered by some not only as a marked character of the human spine but even as peculiar to humanity; other anatomists have denied that this is so, and consider that man and certain of the man-like apes have it in common. In this memoir Prof. Cunningham seems to minimise the importance of the lumbar curve as a distinctive character of any special group. Not only the higher, but also the majority of the lower apes, possess this curve; and, under certain conditions, even some quadrupeds show clear traces of it. In the course of his investigations, Prof. Cunningham has brought many new and interesting facts and phenomena to light. Thus in man and the chimpanzee the quality of this lumbar curve is identical; the only differences are its extent and its development. And then among the members of the human race this curve does not appear to be equally prominent; upon some —as the Australian, the Negro, and the Andaman Islander —the curve is by no means so well marked as it is in the European. Not that the absolute degree of curvature is less in these races, but whereas in the European the bodies of the vertebræ are more or less moulded in adaptation to the curve, in the lower races there is to be found no trace of this. With this subject the first part of this memoir is taken up, and the adaptation of the vertebral bodies with reference to the lumbar curve is considered in a first section. The method of making the measurements, and the results derived from them, are given, and special points in connection with the European and several of the lower races (Australian, Tasmanian, Andaman, Negro, and Bushman) are given. Then follow details of the indices of the lumbar vertebræ in the four man-like apes, as well as in nine of the lower apes. The statement that this curve is more marked in the female than in the male is strongly supported by the evidence adduced in this memoir, and it would seem that the vertebral bodies of the female are moulded more in adaptation to the curve than those of the male.

The second section of this part of the memoir treats of the entire lumbar curve as found in man and the apes. The difficulties in the way of securing accurate curvatures of the living spine seem to be insuperable. Parow, who worked hard on this subject, has signally failed; hence the standard of comparison must be sought for in the dead, and the details of how this has been done are given at some length. Racial differences are next discussed, and the development of the spinal curve is treated at great length, with some excellent illustrations. The condition of the lumbar column in the anthropoid apes is next considered. It was, as we have seen, thought that the lumbar curvature did not exist save in man. Goodsir is positive about it. Sir W. Turner at one time was equally so. Sir Richard Owen denies its presence in the gorilla and orang-utan. Huxley was among the first to assert its existence. Broca and Topinard followed. As to the facts to be seen by frozen sections, Cunningham has not succeeded in getting fresh material for the gorilla; but in the case of the chimpanzee the curve differs but little from that in man. In the orang it is feeble, resembling that in man in some respects, and in others differing from that in the chimpanzee. In a gibbon (*Hylobates agilis*) it stands intermediate between the chimpanzee and orang. In some of the monkeys it is also to be found, and even in some quadrupeds.

In a second part of his memoir, Prof. Cunningham, taking advantage of the same anatomical method which enabled him to make such interesting discoveries as to the extent of the curves of the vertebral column, viz. by sections through recently frozen bodies, has been able to advance our knowledge of the topographical anatomy of the orang, chimpanzee, and gibbon, very considerably. Certain relations of distinct morphological importance cannot by any other method be with accuracy ascertained. The question of how far the cerebrum in the anthropoid apes projects backwards in relation to the upper surface of the cerebellum, was at one time a burning question, and, although fairly set at rest, cannot be said to have been unmistakably demonstrated until now; when the whole of the parts were frozen in their places, sections were made, and we have the results in this memoir amply corroborating previous inductions. Sections of the brain *in situ* in the adult male and newly-born child, in the male and female chimpanzee, female orang, and gibbon, are all figured. Other points in the anatomy of the brain, as the condition of the corpus callosum, and of the hippocampus minor are also alluded to, and a few further details as to other visceral anatomy are given.

The memoir forms a quarto volume of some 150 pages, the typography of which is extremely creditable. The woodcut illustrations and plates are excellent, and the publication of this treatise as a Cunningham Memoir marks the appreciation of its value by the Council of the Royal Irish Academy, as the series of its publication—known as the Cunningham Memoirs, because the expenses thereof are defrayed out of the funds left by a Mr. Cunningham—is reserved only for works which the Council believe contribute some new facts to science.

SCIENTIFIC SERIALS

Bulletin de l'Académie Royale de Belgique, August.—Note on the eruptive rocks of the islands of Marion, Prince Edward, Macdonald, and Heard, by A. F. Renard. These insular groups, which stand on the great submarine plateau in the southern regions of the Indian Ocean, are shown to be entirely volcanic, in no way connected either with the Madagascar group or with the lands of the South Polar seas. Marion and Prince Edward, which were visited and partly explored by Mr. Buchanan, of the *Challenger* Expedition, consist of old plutonic formations, such as feldspar basalts and much more recent black and other lavas. Heard, discovered in 1853 by the American captain Heard and also visited by the *Challenger*, is largely covered with a black volcanic sand formed of grains of magnetite and augite. Elsewhere occur more recent lava formations, which show no trace of the erosive action exercised by the sands on the older rocks. All the specimens collected here belong mainly to the group of feldspar basalts.—On the presence in Belgium of *Bothriocephalus latus*, Bremser, by Edouard van Beneden. A few recent instances are recorded of the presence in Belgium of this human parasite, which is common enough in Holland.—Experimental researches on the influence of magnetism on the phenomenon of polarisation in dielectrics, by Edmond van Aubel. In this second communication the author gives the result of fresh experiments, showing how, by means of a specially-constructed electro-magnet, the electric field which interfered with previous researches may be completely eliminated, while preserving an intense magnetic field. The electro-magnet here described may also be used in ordinary physical experiments, wherever it is necessary to ascertain whether the phenomena observed with the Ruhmkorff and other electro-magnets are due to magnetism and not to the electric field or to the heat of the current traversing the bobbins.

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, November 2.—M. Jurien de la Gravière, President, in the chair.—Fresh communication on rabies, by M. Louis Pasteur. (For summary of this report, see p. 30).—Note on the unequal flow of gases, by M. Haton de la Goupillière. Having, in previous papers, given a complete analytical solution of the various problems connected with this subject, the author here determines the true character of his formulas in their relation to experimental applications.—Remarks on M. Fontaine's report concerning his experiments on the transport of power by electricity, by M. Marcel Deprez. It is pointed out that M. Fontaine's method, which replaces the generator and receiver by a series of machines coupled together in sufficient number to produce the desired effect, so far from being based on any new principle, is the same as that proposed by all electricians who have sought to obtain high tensions without having recourse to the construction of the special machines first suggested by the author. The means employed by M. Fontaine to control simultaneously the four series of generators is also stated greatly to resemble that described in a patent taken out on April 28, 1885, by M. Deprez.—Experimental researches connected with the cerebral functions, by M. Brown-Séquard. These researches have been undertaken in order to show how varied and numerous are the purely dynamic effects proceeding from influences exercised on the encephalon by the sensitive nerves, and on the motor nerves by the nervous centres. Experiments carried on for seven or eight years lead to the general conclusion that all the motor nerves, and nearly all the excitable parts of the nervous centres, may have their excitability greatly modified, even under the influence of remote and slight irritations of the greater part of the nervous system.—On the atomic weight of the oxide of gadolinium, by M. A. E. Nordenskjöld. This compound is not a simple oxide, but consists of the three closely-related oxides of yttrium, erbium, and ytterbium, all with very different atomic weights. Nevertheless, even when derived from quite different minerals occurring in localities far removed from each other, it is here shown to possess a constant atomic weight. On the other hand, this substance is not a true chemical combination, but an isomorphous mixture, thus presenting a new phenomenon in chemistry and mineralogy. It is the only known instance of three isomorphous substances of the class which must still be regarded as elements that are found in Nature not only always together, but always together in like proportions. — On a new function of the otocysts in the invertebrates, by M. Yves Delage. A long series of researches recently conducted at the laboratory of Roscoff leads to the conclusions that these organs, occurring chiefly in the higher crustaceans and mollusks, serve not only as organs of hearing, but also, and perhaps mainly, as organs of locomotion, thus corresponding to the labyrinth of higher animals.—On *Gymnodinium polyphemus*, P., by M. Pouchet. Although hitherto regarded as a member of the vegetable kingdom, this organism presents the remarkable peculiarity of possessing an organ of vision of a somewhat complicated type. It is a headless Peridinian, occurring on the French coast, and, like all Peridinians, feeds on vegetables by endosmotic absorption. The eye, which always occupies a uniform position, is formed of two parts—a true crystalline and a true choroid—and its real character cannot be mistaken, resembling, as it does, in the most striking manner, the eyes of certain worms and Turbellariæ.—Saturation of selenious acid by the bases, and acidimetric analysis of this acid, by M. Ch. Blarez.—On the heat of neutralisation of the homologous or isomerous monobasic acids, by MM. H. Gal and E. Werner. The heat of neutralisation, already determined by Berthelot and Louguinine for formic, butyric, and some other fatty acids, is here determined, together with the heat of dissolution for others, such as isobutyric, isopropylacetic, trimethylacetic, caproic, &c.—Synthesis of pentamethylenediamine, of tetramethylenediamine, of piperidine, and of pyrrolidine, by M. A. Ladenburg.—On two new chloruretted derivatives of methylbenzoyl, by M. Henri Gautier. The process is explained by which the author has obtained a trichloruretted and a bichloruretted methylbenzoyl.—A new reaction of the chloride of aluminium: syntheses of the fatty series, by M. Alph. Combes. The chloride of aluminium, which has effected so many syntheses in the aromatic series, is here for the first time systematically applied to the production of substances of the fatty series.—Hæmatoscopy, a new method of analysing blood, based on the employment of the spectroscope, by M. Hénocque. This method, already tested on 200 subjects, comprises two classes of observations: (1) determination of the quantity of oxyhæmoglobin, or active colouring-matter of the blood, by means of instruments here figured, and named "hæmatoscopes" and "hæmatospectroscopes"; (2) duration of the reduction of the oxyhæmoglobin estimated by spectroscopic examination.—Fresh remarks on the stem of Poroxylon, a fossil Gymnosperm of the Carboniferous epoch, by MM. C. Eg. Bertrand and B. Renault. By comparing together homologous sections of stems of the same order but of different periods, the authors have succeeded in determining the variations introduced by time into the normal stem of this plant.—On a fundamental condition of equilibrium for the living cells of plants, by M. Léo Errera.—Petrographic study of a carboniferous diabase from the neighbourhood of Dumbarton, by M. A. Lacroix. The rock here under consideration, a vertical greenish stratum traversing the old red sandstone, presents an opportunity of studying in a small space the various structural forms which a volcanic rock may assume under the influence of a progressive cooling process. —The dislocations of the globe during recent periods, their lines of fracture, and the conformation of the continents, by M. Jourdy.—On the unity of forces in geology (continued), by M. H. Hermite. It is argued that simple oscillations of sea-level, produced by meteorological causes, would suffice, without having recourse to internal agencies, to explain the *apparent* oscillations of the land in relation to latitude, which are characteristic of the Quaternary epoch.—On the pathologic physiology of the supra-renal capsules, by M. Guido Tizzoni.—On the contractions determined by the currents of polarisation of the living tissues, by MM. Onimus and Larat. The experiments here described place beyond doubt the existence and energy of the currents of polarisation in our tissues, thus exposing the errors of the fundamental experiments carried out by Du Bois-Raymond and most German physiologists.—Note on a remarkable substance collected at Luchon on July 28, 1885, after the fall of a thunderbolt, by M. Stanislas Meunier.

STOCKHOLM

Academy of Sciences, October 14.—Contributions to the anatomy and histology of the limnivore Annelids, by Dr. A. Wirén.—On the electric nature of drift-snow, by Prof. A. Holmgren.—On the work and activity of the Ornithological Committee of the Academy for studying birds of passage, &c., by Prof. F. A. Smitt.—On new acquisitions to the Botanical Garden of the Bergian donation, by Prof. V. Wittrock.—On the lichens of the islands of the west coast of Sweden, by Dr. P. Hellborn.—Contributions to the anatomy of the Marcgraviaceæ, by Hr. H. O. Juel.—Studies of the influence of woods and forests on the climate of Sweden, by Dr. Hamberg.—On remains of Dryasoctopetala, L., in calcareous tuff near Vadstena, by Prof. A. G. Nathorst.—On combinations of phenylmethyl-triazol, by Hr. J. A. Bladin.—On the orbit of the comet 1877, VII., by Dr. R. Larsén.—Demonstration of the proposition that the complete integral of differential equations of the nth order contains n arbitrary constants, by Dr. G. Eneström.

THE ZOOLOGICAL RESULTS OF THE "CHALLENGER" EXPEDITION

Report on the Scientific Results of the Voyage of H.M.S. "Challenger" during the Years 1873-76 *under the Command of Capt. G. S. Nares, R.N., F.R.S., and Capt. F. T. Thomson, R.N.* Prepared under the Superintendence of the late Sir C. Wyville Thomson, F.R.S., &c , and now of John Murray, one of the Naturalists of the Expedition. Zoology—Vols. XV. and XVI. (Published by Order of Her Majesty's Government, 1886.)

VOLUME XV. contains three Reports on the univalve Mollusca collected. The first is a short Report, by Dr. Rudolph Berg, on the Marseniadæ. This family has slowly gathered round the *Helix perspicua* of Linnæus and the *Bulla latens* of O. F. Müller. These species are found in all seas. The shell is either altogether enveloped in the mantle or is very partially exposed, always either calcareous or horny. Six genera are recognised, with 33 species, 11 of which are described and figured as new.

The great bulk of the volume is taken up with the Report, by the Rev. R. Boog Watson, on the Scaphopoda and Gasteropoda. This laborious memoir occupies over 750 pages, and is illustrated by an atlas of fifty plates. Some 1300 species, new and old, were recognised among the mass collected, and there were some 400 indistinguishable forms. In a short appendix, the Marquis de Folin describes and figures the Cæcidæ. The classification adopted, "for want of a better," is that of the Messrs. Adams. The more important of the general conclusions based on the examination of the facts attending the habitat of all the distinguished forms are as follows:—(1) Depth is an important condition in connection with Molluscan life; (2) but temperature is even a more important condition than depth; (3) great differences in either depth or temperature prove barriers to distribution; (4) where these do not exist, there would seem to be no limit to universality of distribution; (5) there are without doubt such universally distributed forms. The author sees no evidence in the oldest or most widely distributed species of any essential, lasting, and progressive change.

The last Report is on the Polyplacophora, by Prof. A. C. Haddon. The number of Chitons collected was, considering the frequency and wide distribution of the group, surprisingly small. Almost the only shore-collecting done during the cruise was on or near coral-reefs, and Chitons would seem to be rare in such places. The really deep-sea forms belong to Leptochiton, of which 4 species were found, and 2 are new. These species were taken at depths of from 60 to 2300 fathoms. Three plates accompany this Report: two are from drawings by the author, and the third, a coloured plate, gives the portraits of the new species by T. H. Thomas.

Volume XVI. contains the four following Reports:—(1) On the Cephalopoda, by W. Evans Hoyle, M.A. Oxon., Naturalist on the Editorial Staff. In a preface to this valuable Report, the author acknowledges the kindly and generous assistance which he received in its execution from Prof. Steenstrup, of Copenhagen, whose knowledge of the Cephalopods is immense, and the collection under his charge is unrivalled. This Report is almost exclusively systematic in its scope, but we are promised a supplement with anatomical details. It commences with a provisional synopsis of recent Cephalopods, which will certainly be of immense value to all workers. While it is true that no systematic treatment of the class can for some time to come be other than provisional, yet the author seems to have taken the greatest pains that his shall be as natural as possible, and until we have a nearly complete knowledge of the life-history of all the forms, more will not be attainable. This list contains 388 species referred to 68 genera. It would have been, we think, an improvement if all those collected during the Expedition had been in this list distinguished by some special mark, as well as having the recorded habitats for each given. Of the 72 species found, some 32 are described as new, and for these 4 new genera and 1 family had to be established. Out of the 388 species, some 60 or 70 had been so badly described as not to be recognisable, but of some of these no doubt the types still remain. Of the new species, none pertain to those great monster cuttles—source of many a battle. The exceedingly interesting genus Cirroteuthis is enriched with three species—one, *C. magna*, being the giant of the group, and measuring 1155 millimetres in length. The type species of this genus (*C. mülleri*, Esch.) was the only one known until 1883, when a second species was described by Fischer, and now (1885) five new species have been described by Hoyle and Verrill. The balance of the evidence seems to be in favour of all the species being deep-sea forms, though at present there are great difficulties in the way of settling the question. A new genus, Amphitretus, is established for a form in which the mantle is fused with the siphon in the median line, so that there are two openings into the branchial sac. This is a quite unique feature among Cephalopods. The species *A. pelagicus* was taken near the Kermadic Islands. It seems strange that but one specimen of *Argonauta argo* was found, for this and other species are not very rare. Of the genus Octopus, 20 species are enumerated, of which 11 are described as new. The one specimen of *Spirula peronii*, found living off Banda, is referred to, but Prof. Huxley is preparing a report on its anatomy. To the already large genus, Sepia, large additions were made, and it is interesting to note that all of the 10 new species were found between Port Jackson (Australia) and Japan. The shell, or sepiostaire, was found to present differential characters in the species, and a series of new terms has been adopted to describe its various parts. The suckers also seem to offer characters of specific importance, and so possibly will the hectocotylised arms when sufficiently known. Two species of Steenstrup's genus Taonius are recorded, one, *T. hyperboreus*, the common North Atlantic form, and the second the *T. (Procalistes) suhmi* of Lankester. Willemoes-Suhm had taken it for a Clionid Pteropod. Lankester described it as a new genus; but the author regards it as but a species of Taonius, and with this Prof. Steenstrup agrees, though he thinks that the specimens found may appertain to two species. As in the case of the Argonaut so in that of the Paper Nautilus but a single specimen was found, and that off Mataku, Fiji Islands. A most important means of obtaining specimens seems to have been by the examination of the stomachs of birds, fish, and Cetacea. These creatures seem to be much more satisfactory collectors than the tow-net, in which, though it was so constantly in use, few Cephalopods were taken. Possibly the immense activity of the cuttlefish will account for this. An atlas of thirty-three plates accompanies this Report.

(2) On the Stomatopoda, by W. K. Brooks, Johns Hopkins University. These Crustacea are in their adult forms inhabitants of shallow water. The collection brought home was but small, and contained no startling novelties, so that at first the author was somewhat disappointed; but this feeling turned to delight when he discovered that the material furnished some excellent opportunities for tracing out, and that with great completeness, the phylogeny and ontogeny of this little order. This order includes about 60 adult species and a vast number of tropical larvæ. The *Challenger* collection of adult forms consisted of only 15 species, 8 of these new, while 2 others had been, to this, very inadequately described; but the collection of pelagic larval Stomatopods was peculiarly rich, and in Mr. Brooks's hands it has yielded the material for tracing the history of several of the larval types, and also, more remarkable still, for establishing in every genus except one the connection between the adults and their larval types. The larval history of these Stomatopods has been one of the most puzzling problems in morphology, and the very admirable researches of Claus had been the only guide. Though often in error, Mr. Brooks confesses that without Claus's memoir to guide him his own labours must have failed. Unlike most Malacostraca, the Stomatopods, instead of carrying their developing eggs about with them, deposit them in their deep and out-of-the-way burrows under the water. They are thus most difficult to procure, and so difficult to rear that probably not a single instance of a young Stomatopod being reared from the egg is known. The growth of the larvæ is slow, and the larval life long, and, as they are as independent and as much exposed to changes in their environment and to the struggle for existence as the adults, it has come to pass that they as larvæ have undergone countless modifications which have no reference to the life of the adult, and are therefore unrepresented in the adult organism, in which the larvæ differ *inter se* more than the adults do, thus reversing the general rule. The history of each larval type has thus to be traced by the selection and comparison of those larvæ which belong to the series, and in doing this the author was partly guided by general resemblances and partly by a series of comparative measurements. The differences between the genera are slight, and all can be grouped into a single family, Squillidæ. In the description of *Lysiosquilla excavatrix* we have a very interesting account of its habits. The Report concludes with an elaborate account of the various larval forms and their adult connections. Sixteen plates accompany the Report.

(3) On the Reef Corals, by John J. Quelch, B.Sc. Lond. The author apologises for this Report of just 200 pages being so short, as he was limited both as to time and space. A careful perusal of the memoir inclines us to the opinion that no such apology is needed. Without being a monograph, the Report forms a most important contribution to our knowledge, and this not only of the distribution of the reef corals, but also, in many instances, of their structure. The term reef coral is undoubtedly vague, but the forms described in this report belong almost entirely to the Reef Madrepores, descriptions of some few species of Millepores being added. The collection made contained representatives of 293 species referable to 69 genera, and many of the species were represented by series of specimens often presenting a considerable degree of variation. As a proof of how little known are the corals of the Pacific and Indo-Pacific Islands, it may be mentioned that 71 of the new species were found in these regions, while but 2 were from the Atlantic. No attempt has been made to describe the soft parts of the specimens. Special attention is directed to the fact that the descriptions of species apply to specimens in which the calycles are perfect; in most museum specimens these are generally to be found greatly injured, and then it is often impossible to distinguish between closely-related forms. In the treatment of the distribution of these corals, lists are given of the species obtained at each locality, together with lists of the new species, and of old species recorded from the stations for the first time. While the classification adopted is on the main based on that of Milne-Edwards and Haime, a rather startling novelty in arrangement is the merging of the Madreporia Rugosa with the section of Madreporia Aporosa. The detailed reasons for this are given on pp. 40-43; and as a result the author considers that there is not a single characteristic of the old group Rugosa which will essentially separate forms usually included under it from the more typical Astræids. Thus in many Astræids the septa present are not multiples of six, while in some typical Cyathophyllidæ the septa are simply radially arranged, without any indication whatever of a tetrameral type. Again, the presence of a fossula is scarcely even of generic value; and as to the presence in the adult rugose coral of but two sizes of septa, this phenomenon is not always present in the species, and is to be met with in some typical Astræids; while as to the tabulæ, which are no doubt very characteristic of the Rugosa as a group, still even these are present in some Astræids, and absent in some Rugosa. In a striking new Madrepore, *Moseleya latistellata*, the characters are to a marked degree intermediate.

There is yet a great deal of work to be done ere the distributional areas of the reef corals is known. Probably the coral fauna of no district, unless that of the Red Sea, has been fairly worked out. It was in the nature of things that the cruise of the *Challenger* could not, from the shortness of its sojourn at any one coral district, do much in this direction. Still some few facts of great interest have been brought to light, one of the most remarkable being the occurrence of an undoubted reef-building species, *Manicina areolata*, in Simon's Bay, between lat. 34° and 35° S., at a depth of from 10 to 20 fathoms, and at a temperature of 65° F., and this is all the more peculiar, as this coral is a well-known West Indian reef-building form. Another coral, *Cladocera arbuscula*, was also found at Simon's Bay, though a West Indian species.

Notes and descriptions of eight species of Millepora are given in an appendix. One new species is called after Mr. Murray, being the one on which he saw the living zooids of this remarkable group of Hydroids. It was *M. nodosa*, occurring at Tahiti, that afforded Prof. Moseley the material for his brilliant confirmation of the observations of L. Agassiz. Twelve plates, the figures on which are beautifully executed by Mr. H. Gawan, accompany this Report.

The concluding Report in this volume is by Prof. Sir William Turner, being on the Human Crania, &c., collected during the cruise. This forms Part 2, being on the bones of the skeleton, and is an Essay on the Comparative Osteology of those Races of Men whose bones are described in the Report, for it incorporates the study not only of the material collected during the cruise of the *Challenger*, but that brought together by the authors' eminent predecessors in the Chair of Anatomy in the University of Edinburgh.

Just a century ago Camper pointed out some of the differences existing between the pelvis of a Negro and a European, and since then a vast amount of information on the subject has been accumulated, and so far as the races described in this Report are concerned, it has been exhaustively treated by Sir W. Turner. He classifies the pelvis into three groups: dolichopellic, with a brim index above 95; mesatipellic, with a brim index from 90 to 95; and platypellic, with index below 90. As to the race and age characters of the pelvis, the details, however interesting, are too technical to be abstracted. In reference to the question of how far the mode of life may act as modifying the transverse diameter of the pelvic brim, we may add that the expression "to sit on one's hunkers," would be readily understood in the North of Ireland, where it is an attitude strictly forbidden to young people. In the section treating of the spinal column, the subjects of peculiarities of individual vertebræ and the lumbar curve are investigated; and in another section the scapula, inferior and superior extremities, are examined. In a concluding section we have a general summary, and an appendix to the first part of the memoir on the "Human Crania," in which some additional details are given of some crania from Australia, the Sandwich Islands, New Guinea, and Fuegia. An index to both parts also accompanies this Report, which is illustrated by three plates of the pelves of different races.

The greater portion of the manuscript of these two large volumes was handed to the editor between July 1885 and July 1886, and the editor is to be congratulated on the successful manner in which this immense amount of scientific matter has been seen through the press.

ELEMENTARY DYNAMICS

Lessons in Elementary Dynamics. Arranged by H. G. Madan, M.A., Assistant Master in Eton College. Pp. 180. (Edinburgh: W. and R. Chambers, 1886.)

In this little book the author has provided teachers of elementary mechanics with a rich storehouse of materials for experimental demonstrations, although the work is not quite satisfactory in some other respects. His endeavour has been to explain some of the properties of matter, Newton's laws of motion, and the modern conceptions of energy and work, in such a manner as involves only the most elementary knowledge of mathematics. Thus symbolical reasoning and formulæ are dispensed with, and nothing assumed beyond a knowledge of arithmetic and a little easy geometry. There is a successful attempt made to arouse a real interest in the subject by continual reference to phenomena of every-day life, and especially by illustrations drawn from the sports and games of the pupils. In some cases detailed instructions are given for performing the experiments. These are valuable, and similar aid might with advantage be provided in many other instances.

The author is of opinion that mechanics ought to have the first place in a boy's scientific education. This position would be strengthened, if some series of simple experiments, to be performed by the pupils themselves, were provided, and regarded as essential.

Some expressions, such as "above," "below," "on the same level," which are usually left undefined, have their exact scientific meaning pointed out. On the other hand, there is occasionally looseness and confusion in the use of technical terms. For example, in Section 103 we read: "Momentum is the term used to express the *force* with which anything is moving." In Section 159 we have the accurate statement that, by finding the momentum of a body, we learn what *impulse* has been applied to it: here the accepted expression for the time-integral of a force is used, but we do not notice any definition of the word "impulse"; and the exposition of the second law of motion appears vague in consequence. Similarly, the *force* exerted in throwing a cricket-ball is spoken of in Section 156, where the time-integral of the force is in question.

Section 302 is devoted to the "exact valuation of the energy in a moving body," and the usual expression—energy = $\frac{1}{2}$ (mass × velocity^2)—is obtained, but by a process which is at least startling. Witness these statements:—"If the work could be done *in an instant*, the energy would be exactly expressed by the product of the mass × velocity^2;" and again, "The whole amount of work which a moving body can do in the time during which its motion is being stopped will correspond to the *average* or *mean* amount of energy between that which it has at the beginning of the time and that which it has at the end of the time." *Unde, quo veni?*

After the preceding, it is a small matter to refer to Section 311, where this statement occurs: "The motion of the pendulum is an accelerated motion, and, as in al other uniformly accelerated motions, the spaces described are as the squares of the times." Here, of course the reasoning is fallacious; and, although the proof intended is sound, it involves the doctrine of limits, and wants development. It is surely better at this stage of the pupil's progress to rely on the experiments in Section 312.

There is an appendix on the metric system, and, in conclusion, a dozen pages of questions and exercises on the several chapters of the book. A. R. W.

OUR BOOK SHELF

Food-Grains of India. By A. H. Church, M.A. (London: Chapman and Hall, 1886.)

A WELL-WRITTEN, well-illustrated, and well-turned-out volume. Its thinness only enhances its elegance. Its illustrations, by Mr. G. W. Ruffles, are charming, clear, without hardness, and life-like. The text is interesting, and the number of food-grains described in excess of what most of us were aware existed. Prof. Church commences his work by what must have been to him a familiar task—describing the chief constituents of food, splitting up the sugars into their groups, and pointing out the differences between true nutrients and food-adjuncts. Part 2 is devoted to dietaries and rations. With Part 3 commences the peculiar merit and *raison d'être* of the work. After some remarks upon cereals generally, the reader is introduced *seriatim* to no fewer than twenty-three cereals, the only member of the group conspicuous by its absence being rye—a grain which occupies a very important place in Europe. The presumption is that it does not occur in India, but such a presumption surely presumes too much. Wheat is described as an annual grass of unknown origin, but we scarcely see why this *nescience* as to the origin of wheat should be especially set forth. Are we to infer that barley, oats, maize, rice, the millets, &c., are annual grasses of known origin? If so, would that the Professor had devoted a few lines in each case to this particular point! The origin of our food-grains is a deeply interesting subject, veiled, we are afraid, for the most part in mist, and only conjecturally outlined.

The author disclaims any special originality, and duly credits the works of Dr. Forbes Watson, and Messrs. Duthie and Fuller, as well as other authors, as sources from which he has industriously gathered information. Messrs. Duthie and Fuller's work, however, dealt but little with the chemistry or physiology of the plants they described, and they treated more exclusively of the cultivation of the various crops.

The interest of Prof. Church's book lies in the illustrations, which are super-excellent; in the analyses, many of which were made in the author's own laboratory; in fixing the nutrient-ratio and nutrient-value of so many foods; and, lastly, in the comprehensive view given of Indian cereal and other crops. The Indian local names and Sanskrit equivalents are also interesting. These are taken by our author on trust, but all or many of them also occur in Mr. Duthie's book, which would be a guarantee of their correctness.

JOHN WRIGHTSON

Tobacco a Farmer's Crop. By Philip Meadows Taylor. (London: Edward Stanford, 1886.)

THIS is a small book of seventy pages. The first half is occupied by pleasant matter relating to the history of tobacco in Europe not strictly or seriously relevant to the title. The latter half redeems the whole from the stigma of being unpractical. An interesting account is given of the despotic regulations of the "Régie des Tabacs," a Government Department which grants licenses for growing, manufacturing, and selling tobacco throughout France, and whose powers extend to the nomination of the cultivators, the variety of tobacco to be grown, the number of plants per hectare, and even the number of leaves permitted per plant, so that the unfortunate cultivator may and must give a perfectly accurate account of his yield down to a single leaf. The methods of cultivation followed in France are described plainly and apparently practically. The important question as to whether tobacco can be grown profitably in England is answered unhesitatingly in the affirmative, and a sensible scheme is propounded for bringing its culture into harmony with the Excise. The coldness exhibited by our Royal Agricultural Society towards the tobacco movement last April is strongly animadverted upon. As to our climate, Mr. Taylor writes as follows:—"It is stated to be too cold, too damp, too uncertain in England to allow of the introduction of the proposed culture. I cannot conceive or allow that there can exist any sensible difference between the climate of the southern counties of England and that of Picardy and Flanders. I do not take notice of Prussia and even Russia, where tobacco is grown. I believe that the general climate in Southern England is more genial than in the countries across the Channel, and I feel confident that in the said southern counties of England and in Ireland tobacco could be advantageously grown. I recall my former statement that the plant is only on the ground from June to September: cold winters, early frosts, and November fogs have naught to do with the question." The author does not appear to take into account the comparative coolness of the summer months in England, which has always prevented the successful growth of maize, vines, and probably tobacco also. This very readable little book, with its unstudied side-lights upon French rural life, and its pleasant style, may be recommended without any hesitation to the reading public.

JOHN WRIGHTSON

Marion's Practical Guide to Photography. (London: Marion and Co., 1886.)

HERE we have a very good book, which contains all necessary information and useful hints for those who are practising the art of photography. The whole process is gone through in a very clear and easy way. Extra chapters are given on different parts of the subject, such as photographic optics, re-touching, portraiture, &c. On p. 95 a table of exposures is added, preceded by explanations, taking into consideration all the variations of scenes and subjects which the amateur is likely to come across. The manufacturers deserve great credit for publishing a book in which the best way of using their apparatus is described; a book published under such conditions ought to be truly practical, and one would think that the manufacturer of bad apparatus would not be too anxious to teach his customers how to find it out.

Lecture Notes and Problems on Sound, Light, and Heat. By Charles Bird, B.A., F.G.S. (London: Relfe Bros., 1886.)

FOR students who are attending lectures on these subjects this book will be very useful, as it contains the chief fundamental formulæ, set out in a very clear manner, and it is very compact, capable of being put into one's pocket without inconvenience.

Bicycles and Tricycles for the Year 1886. By H. H. Griffin, London Athletic Club. (London: L. Upcott Gill, 1886.)

NOW that cycling has become so general, and consequently the cycle industry increased so largely, a book on the subject will doubtless be most welcome. We have here one which gives a *good* description, and in many cases a woodcut, of every known make, with the exception, perhaps, of one or two very new patterns which have been introduced very recently. We need not enter into the details from the scientific point of view, as they have been previously described (NATURE, vol. xxxiii. p. 132). A description of different varieties of bells, lamps, &c., is also given. Great pains seem to have been taken by the author to bring the book up to date, and to give an accurate account; each machine, as he tells us, having been examined by himself.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Extension of the Corona

IN reference to the failure of observers at the late eclipse to note any such extension of the corona as was seen in 1878, I desire to add my testimony to Mr. Common's opinion (NATURE, vol. xxxiv. p. 470), that the conditions of the sky must have been wholly different; and where the visibility of the corona is in question, the atmospheric diffusion is all-important.

We have a most trustworthy criterion of the amount of diffused sky light in the visibility of the moon's limb outside the sun on the coronal background. This appears not to have been observed at all last August, and it may be useful to recall what it looked like under certain almost ideal conditions, which are not likely to recur.

On July 29, 1878, I observed it in the remarkably clear air of Colorado, and at an altitude of over 14,000 feet, on Pike's Peak, and have a vivid recollection of its appearance then. After totality, and while writing my notes, I heard a call from some bystander of "Look at the moon!" and glancing up from the paper (with an eye which could not have been in a sensitive condition), saw the moon's limb outside the sun, most conspicuously defined by a band of pearly light, which faded outward, but whose visible width can be estimated from the fact that though I went on intermittently with my notes, and took no other precaution to shield the eye than keeping it in the shadow cast by my telescope stand, the limb continued in my view under these unfavourable circumstances for *four minutes and twelve seconds* after totality was over. A similar duration was recorded by Gen. Myer, the Chief Signal Officer of the United States, who observed near me; and others at a lower altitude certified to having observed it over three minutes. Something is due to the increased sensitiveness of the eye after the darkness, but there is no doubt that, with even the slight rest of the retina which totality afforded, the phenomenon was such a salient one as to force itself on the attention of those not regarding it.

This is for a very exceptionally pure sky, of course; but if, as is stated, observers specially seeking it could not even see the limb a little outside the sun (where the corona is brightest) last August, it seems clear that no conclusions as to its non-visibility under any ordinary means are to be drawn from negative evidence of such a kind. S. P. LANGLEY

Allegheny Observatory, Allegheny, Pennsylvania

The Astronomical Theory of the Great Ice Age

IN your issue of November 4 (p. 7), my friend Mr. W. H. S. Monck asks one or two questions relative to the paper on "The Astronomical Theory of the Great Ice Age" which you did me the honour to reprint.

I take as a convenient unit the mean daily sun heat on one hemisphere. The amount of this unit is indicated by the fact that it continuously maintains the earth's temperature some 300° more or less above what it would be were the sun's heat withdrawn.

The calculations I gave showed that in the glacial winter the mean daily receipt of heat sunk to ·68 of a unit, while in the brief glacial summer the mean daily receipt was 1·38 unit.

Considering the magnitude of the unit, it is obvious that fluctuations like this must correspond to vast climatic changes of the kind postulated in the Ice age. Here it seems to me lies the great originating cause of the Ice age, and to dwell on the minor phenomena merely obscures the real point.

If it be said that no great climatic change takes place because the total sun heat in the year remains the same, then I remark, as I did at the Royal Institution, that on this principle it would be the same thing to give a horse 15 lbs. of oats a day for six months and 5 lbs. a day for the other six months as to give him 10 lbs. of oats a day all the year round. ROBERT S. BALL

The Observatory, co. Dublin, November 11

P.S.—I take this opportunity of correcting a misprint in my paper as given in NATURE (vol. xxxiv. p. 608). The maximum number of days' difference between summer and winter is 465 × eccentricity.

Abnormality in Cats' Paws

AMONG the many interesting features suggested by the genealogical table in last week's NATURE (p. 40), showing the persistence of abnormality in the number of toes on a cat's paw, there is one the significance of which seems not to have occurred to, or to have been passed over by, Mr. Edward Poulton. The peculiarity I refer to is the larger percentage of abnormality among the female offspring than among the male. Taking "Tabby V." as a starting-point, and leaving out one abnormal kitten of which the sex was unnoted, as well as the families of which no particulars are given, the total number of descendants in the table is 36, of which 12 are males and 24 females. Of the 12 males, 5 are normal and 7 abnormal, or $41\frac{2}{3}$ and $58\frac{1}{3}$ per cent. respectively; and among the 24 females 7 are normal and 17 abnormal, or $29\frac{1}{6}$ and $70\frac{5}{6}$ per cent. respectively. Or, to put it in another way, among the 12 normal kittens 5 are males, 7 are females, or $41\frac{2}{3}$ and $58\frac{1}{3}$ per cent. respectively, instead of $33\frac{1}{3}$ and $66\frac{2}{3}$ per cent. as it should be; and among the abnormals 7 are males and 17 females, or $29\frac{1}{6}$ and $70\frac{5}{6}$ per cent. instead of $33\frac{1}{3}$ and $66\frac{2}{3}$.

This would seem to indicate either (1) that there is a greater tendency among the male offspring than among the female to revert to the normal condition, or (2) that there is a tendency among the offspring to inherit rather the peculiarities of the parent of their own sex—the male parent in all cases in the table being assumed to be normal. If rather, probably the former, though the latter could easily be tested by a similar set of observations with cats, the male parent of which was abnormal, the mothers being in each case normal.

J. HERBERT HODD

Hatton Garden, London, E.C., November 15

Abnormalities in the Vertebral Column of the Common Frog

IN preparing skeletons of the frog, my students came across the following abnormalities in the vertebral column, a record of which may be not without interest:—

(1) In a large *Rana temporaria*, the centrum of the eighth vertebra, instead of being biconcave (amphicœlous), is concavo-convex (procœlous), like that of the preceding vertebra. This abnormality I have observed before.

(2) In a medium-sized *Rana temporaria*, the eighth and ninth vertebræ are both abnormal. The ninth vertebra has well-developed only one transverse process (the right) for articulation with the ilium. The other (the left) is quite small and ill-shapen; there is is no anterior zygapophysis on this side. The centrum is anteriorly convex on the right side and concave on the left side. Posteriorly, there is on the right side a convex articular surface for the urostyle; but on the left side the articular surface is ill-developed and irregular. In the eighth vertebra, the left transverse process is abnormally large and strong, has a marked backward direction, and has taken on itself the sacral function on this side, articulating with the ilium. The right transverse process is nearly, but not quite normal. There is a right, but no left, posterior zygapophysis. The anterior end of the centrum is normally concave; but the posterior end is convex on the left side and concave on the right side. The urostyle and the ilia are slightly modified in accordance with the abnormalities of the vertebræ. C. LLOYD MORGAN

University College, Bristol

Influence of Wind on Barometric Readings

ALLOW me a few words of supplement to Prof. Abbe's useful letter in NATURE of November 11, p. 29.

Sir H. James's paper is perhaps better known on this side of the Atlantic than Prof. Abbe thinks; but there undoubtedly is too great a tendency to rush into print without previously reading up what has been done. The great bibliographical work which the Signal Office has in hand will do more to check this evil than anything which could be suggested, and hence its enormous importance.

As regards the application of suction to anemometers, no reference is made to that of Bourdon,[1] of which my friend Dr. Fines was recently kind enough to show me a very fine specimen at work at his observatory at Perpignan.

The Cowl Committee of the Sanitary Institute, far from being (as has been imagined) asleep or dead, has been very hard at work, and will in a few months report the result.

I sincerely hope that Lord Rayleigh will accede to Prof. Abbe's suggestion, but in the interim I append the report of Lord Rayleigh's Southampton paper which appeared in the *Meteorological Magazine* for October 1882, p. 130:—

"'On the Effect of Wind on the Draught of Chimneys,' by Prof. Lord Rayleigh, F.R.S.

[1] See also Laughton, "Historical Sketch of Anemometry," *Quart. Journ. Roy. Met. Soc.* vol. viii. (1882), p. 177.

"The author said that the draught diminished as the direction of the wind was more and more downwards, but did not go backwards until the inclination amounted to about 30°. The maximum up-draught would occur, not, as was often supposed, with a direction of wind vertically upwards, but with one making an angle of about 30° with the vertical. A chimney with a T-piece at the top never produced an unfavourable effect on the up draught, and only in one case failed to produce a favourable one. With a T-piece to which was affixed vertical ends, every wind met with would have a favourable effect, and no wind known would have an unfavourable effect.

"Prof. De Chaumont thought that vertical ends increase the resistance of the up-draught, and described a chimney with a lamp-shade-like top and conical cap, with which it was impossible to get a down-draught." G. J. SYMONS,

62, Camden Square, N.W. Registrar Sanitary Institute

Barnard's Comet

I WONDER that more has not been written about Barnard's comet (*f* 1886). On the 9th, at 17h. 50m., in spite of the strong twilight, it was plain with the naked eye as a star. I did not notice its exact brightness, but it was perhaps equal to ρ Virginis. With the telescope its head was about 8′ diameter, and it had two faint tails at about position-angles 250° and 300°. The former, which was the brighter at its origin, was ½° long, and was straight; the latter I believe was curved, and was 1½° long. T. W. BACKHOUSE

Sunderland, November 11

Aurora

LAST evening (November 2), between the hours of seven and eight o'clock, a bright anrora was visible in this vicinity. At intervals later in the evening, patches of cirrus clouds in the northern sky became luminous. The disturbance of the suspended magnet was at its height early in the evening, when the aurora was brightest. It is interesting to note the fact that this aurora was twenty-six days removed from that of October 7 and 8, corresponding to the time of the revolution of the sun on his axis. It is noteworthy, also, that very near to the time of the appearance of each aurora there was a slight renewal of earthquake activity in South Carolina and other localities.

Lyons, New York, November 3 M. A. VEEDER

"Lung Sick"

DR. EMIL HOLUB, in writing to me a few months ago from Panda-ma-Tenka, Albert Country, Zambesi, mentions having treated his cattle in a similar manner to that referred to in NATURE of the 11th inst. (p. 29). He says:—

"Shortly after I started northward from the Vaal, a contagious disease broke out among my cattle; there was any amount of sickness among the numerous trains (forty teams a day) going to the Diamond Fields, but I could get no clue to the lameness of the front legs of my bullocks for a long time. Having shot one, the disease proved to be a contagious pleuro-pneumonia, similar to the 'lung sick' so prevalent in this neighbourhood, affecting hips and shoulder-blades, causing lameness. The lungs were partly destroyed, but the animal had but little cough. I disinfected the whole herd, and vaccinated the healthy as well as the sick. The end of the tail was pierced with a narrow-bladed dagger, and a piece of lung full of virus inserted and then bandaged. The second vaccination effectually prevented the spreading of the disease for the whole journey, even in native locations similar to the Bechuanas, in which we were surrounded with 'lung-sick' cattle dying near our encampment." PHILIP J. BUTLER

55, De Beauvoir Road, London, N., November 13

PAUL BERT

PAUL BERT, who has died at his post as Governor of Tonquin, was born at Auxerre in 1833, graduated Doctor of Medicine in 1863, and Doctor of Science in 1866. Obtaining a professorship in the Faculty of Science at Bordeaux, M. Bert devoted himself especially to physiology, and in 1869 he obtained the Chair of General Physiology in the Faculty of Science at Paris. He continued here his experiments on the influence of changes of barometric pressure on life, and presented a series of papers on the subject to the Academy of Sciences, which awarded him, in 1875, its great biennial prize of 20,000 francs. He entered political life in 1870, and has all along been known as an advanced Radical. He, however, never lost his interest in science; he did much to promote education in France, and took an active part in the legislative movement which obtained for M. Pasteur an annual pension of 12,000 francs as a national recompense. M. Bert was elected President of the Biological Society in 1878, in succession to Claude Bernard, whose most brilliant pupil he was, and more recently was admitted to the Academy of Sciences. In Gambetta's Cabinet of 1881 he was Minister of Public Instruction, and a few months ago accepted the post of Governor of Tonquin, where one of his most notable acts was the founding of a Tonquinese Academy. M. Bert's papers on "Barometric Pressure" were published as a separate volume in 1877, and his lectures at the Museum of Natural History were in 1869 published under the title of "Leçons sur la Physiologie Comparée de la Respiration." He also issued, in 1869-70, "Notes d'Anatomie et de Physiologie Comparées." For many years he had charge of the scientific department of the *République Française*.

At the sitting of the Academy of Sciences on Monday, the President, M. Jurien de la Gravière, expressed regret that politics had diverted M. Paul Bert from physiology; and M. Vulpian remarked that his death, though glorious for the country, was a calamity for science, his numerous memoirs having placed him among the first physiologists of the age. The Academy adjourned in sign of mourning.

THE RECENT WEATHER

AT the close of a short period of somewhat unusual weather conditions, it may be worth while to call attention to the more prominent features of those conditions.

Cyclonic systems, some of wide, some of small dimensions, have been primarily developed over Western Europe in unusually large numbers. Opportunities for studying those atmospheric conditions from which barometric depressions originate within the area of our European stations are by no means very rare, but they are nevertheless sufficiently scarce to merit careful scrutiny at the hands of every student of weather knowledge. So much is this the case that a meteorologist of eminence made, some years since, the statement that no one had ever been present at the birth of a storm.

Considering the disastrous nature of the floods, the sloppiness of earth and sky, and the general misery in the aspect of things, which characterise the event, few of us can wish to be very frequently spectators of it. But when it occurs, the conditions accompanying it should be carefully attended to. These may perhaps be briefly summarised thus:—

(1) Barometric depressions are primarily developed over a region where atmospheric gradients are slight, the exceptions to this rule being those systems (secondary or subsidiary, as they are termed) which first appear as loops or bulges in the isobars of a large pre-existing cyclone.

(2) They originate either in the rear of a depression which has already passed away or in the inter-space between two large anticyclones, and more especially when the anticyclones are so large that this inter-space constitutes what is called a "trough" of relatively low pressure.

(3) They are preceded and accompanied by an enormous condensation of vapour into cloud.

(4) They do not, at the moment of their birth, appear

to affect the upper currents of the atmosphere, but, if growing large, soon afterwards do so, in such a manner that the hypothetical isobars at the level of the cirrus appear to be bent into a V-shaped hollow from the great polar depression to a point nearly above the centre of the circular depression at the earth's surface.

Of the depressions lately developed near the British Isles and over the south-west of France, the greater number originated in "troughs" of relatively low pressure, such as have been above alluded to: and their movements may be said to have been unusually erratic. Yet they obeyed the ordinary rule of progression, in so travelling, as to have the highest general pressures on the right of their course. Thus, those depressions which originated near the east side of a "trough" lying north-north-west to south-south-east, tended to move to north-north-west, while those which originated on the other side of the "trough" travelled in the contrary direction. On the 10th inst., Great Britain lay between two depressions travelling in parallel but opposite directions, these directions being transverse to the mean direction of movement prevalent at this season of the year. The same phenomenon was repeated on the 12th inst. It is now more than twenty years since I began constructing daily charts of the directions taken by European depressions, and during the whole of that period there has been no instance entirely comparable with these.

We must wait for reports from a very extensive portion of the earth's surface before a comprehensive study of these phenomena can be undertaken. Two questions, so correlated that they may require but a single answer, are of prime importance:—What causes the abnormal, but temporarily persistent, determination of aqueous vapour to certain portions of the globe? What causes the abnormal, but temporarily persistent, occupation of certain portions of the globe by anticyclonic systems?

W. Clement Ley

THE WORK OF THE UNITED STATES FISH COMMISSION[1]

A BRIEF memorandum of what the U.S. Fish Commission hopes to accomplish in time, in connection with its mission, is as follows:—

(1) In the department of investigation and research there is yet to be carried out an exhaustive inquiry into the character, abundance, geographical distribution, and economical qualities of the inhabitants of the waters, both fresh and salt. The subject is practically unlimited in extent, and, so far as the ocean is concerned, has scarcely been touched. With the powerful apparatus, however, at the command of the Commission it is expected that much progress will be made year by year, and that the publication of the results and the distribution of duplicate specimens to colleges and academies in the United States will be carried out on a large scale, so as to meet a large and increasing demand from teachers and students.

(2) A second object, in connection with the sea fisheries, is the improvement of the old methods and apparatus of fishing and the introduction of new ones.

The work of the Commission in bringing to the notice of American fishermen the importance of gill-nets with glass-ball floats for the capture of codfish has already revolutionised the winter cod-fishery industry in New England. Looked upon almost with ridicule by the Gloucester fishermen, when first brought to their notice by the Commission, these nets have come rapidly into use, until at the present time they represent the most important element in the winter fisheries, the number of fish taken being not only much greater than heretofore but the fish themselves of finer quality.

[1] From the "Report of the U.S. Commission of Fish and Fisheries" (Washington, 1885).

The ability to maintain a successful fishery without the use of bait is of the utmost importance, in view of the fact that when the cod are most abundant bait is almost unprocurable. Other forms of apparatus of less importance have also been introduced, and a constant look-out is maintained, by correspondence and otherwise, in connection with the improvement of fishing machinery.

(3) Another important point for consideration is that of improvement in the pattern of fishing vessels. There is annually a terrible mortality in the fishing crews of New England, especially those belonging to the port of Gloucester, to say nothing of the total loss and wreck of the fishing vessels and their contents. There has gradually developed in connection with the mackerel and cod fisheries of New England a pattern of vessel which, while admirable for speed and beauty of lines and of rig, is less safe under certain emergencies than the more substantial and deeper vessel used abroad, especially in England and Scotland.

The subject of the best form of fishing vessel has been intrusted to Captain Collins, of the Commission, himself a most experienced fisherman, and, after a careful study of the boats of all nations, he has prepared a model which is believed to combine the excellences of both English and American vessels.

An appropriation will be asked from Congress for means to construct an experimental vessel and test its qualities; but until a successful experiment has been made it will be difficult to induce the fishermen to change their present form of construction.

(4) The fourth object of the Commission is to determine the extent and general character of the old fishing localities and to discover new ones. There is no doubt whatever that there still remain many important areas, even in the best-known seas, where the codfish and the halibut will be found in their former abundance. There has never been any formal investigation on this subject, and the banks that are known have been brought to light purely by accident. It is believed that by a systematic research and a careful survey the area of known grounds can be greatly extended.

There is very great reason to hope for successful results from this inquiry in the waters off the South Atlantic coast and in the Gulf of Mexico. These regions, the latter especially, may be considered as practically unknown, the few established localities for good fishing being in very small proportion to what must exist. It is here that the service of the fishing schooner referred to above, if means can be obtained to build it, will be brought into play, and it is not too much to hope that an industry will be developed that will represent to the Southern and South-Western States the same source of income and occupation that the mackerel, cod, and halibut furnish to the fishermen of New England.

(5) There is also much to be learned in the way of curing and packing fish for general and special markets. The American methods have grown up as a matter of routine, and are adapted to only one class of demand. There are, however, many modes of preparation which can be made use of to meet the wants of new markets; and thus we can enter more efficiently into competition with European nations for European trade, as well as for that of the West Indies and South America.

A great advance has already been made towards this desired improvement since the Centennial Exhibition of 1876, where many methods of curing and putting up fish were shown in the foreign sections that were almost entirely unknown in America. Notable among these were the preparations of sardines and other species of herring in oil, as well as in spiced juices. Quite recently this industry has been well established in Maine, amounting to a value of millions of dollars, and there are many other parts of the country where the same work can be done with other kinds of fish. The whole subject is receiving the careful consideration of the Commission, and numerous facts bearing upon it have been announced in its reports and bulletins.

(6) The work of increasing the supply of valuable fishes and other aquatic forms in the waters of the United States, whether by artificial propagation or by transplantation, although very successful, may be considered as yet in its infancy.

It must be remembered that the agencies which have tended to diminish the abundance of the fish have been at work for many years and are increasing in an enormous ratio. This, taken in connection with the rapid multiplication of the population of the United States, makes the work an extremely difficult one. If the general conditions remained the same as they were fifty years ago, it would be a very simple thing to restore the former equilibrium.

At that time, it must be remembered, the methods of preservation and of wholesale transfer, by means of ice, were not known, while the means of quick transportation were very limited. Hence a small number of fish supplied fully the demand, with the exception, of course, of species that were salted down, like the cod, the mackerel, and the herring (including the shad). Now, however, the conditions are entirely changed. The whole country participates in the benefits of a large capture of fish, and there is no danger of glutting the market, since any surplus can be immediately frozen and shipped to a distance, or held until the occurrence of a renewed demand.

Another impediment to the rapid accomplishment of the desired result is the absence of concurrent protective legislation of a sufficiently stringent character to prevent unnecessary waste of the fish during the critical period of spawning, and the erection or maintenance of impediments to their movements in reaching the spawning-grounds. This is especially the case with the shad and the salmon, where the simple construction of an impassable dam, or the erection of a factory discharging its poisonous waste into the water, may in a few years entirely exterminate a successful and valuable fishery.

It is to be hoped that public opinion will be gradually led up to the necessity of action of the kind referred to, and that year by year a continued increase in the fisheries will be manifested. Even if this does not occur as rapidly as some may hope, the experiments so far furnish the strongest arguments in favour of continuing the work for a reasonable time. A diminution that has been going on for fifty or more years is not to be overcome in ten, in view of the increasing obstacles already referred to.

Among the species an increase of which in their appropriate places and seasons is to be hoped for, in addition to those now occupying the attention of fish-culturists, are the cod, the halibut, the common mackerel, the Spanish mackerel, the striped bass, or rockfish, &c.

One of the most important, and at the same time among the most promising, fish is the California trout, with which it is hoped to stock large areas of the country. Its special commendations are mentioned elsewhere in this Report.

Another fishery earnestly calling for assistance, and capable of receiving it, is that of the lobster, the decrease of which has been very marked. The experiments of the Fish Commission suggest methods by which the number can be greatly increased. Something, too, may be done with the common crab of the Atlantic coast and its transfer to the Pacific. Some kinds might also be advantageously brought to the eastern portion of the United States from the Pacific coast and from the European seas.

A subject of as much importance as any other that now occupies the attention of the Fish Commission is an increase in the supply of oysters. In no department of the American fisheries has there been so rapid and alarming a decrease, and the boasted abundance of this mollusk on the Atlantic coast, especially in Chesapeake Bay, is rapidly being changed to a condition of scarcity which threatens practical extermination, as is almost the case in England. A fishing industry producing millions of dollars is menaced with extinction, and needs the most stringent measures for its protection.

The U.S. Fish Commission has been very fortunate, through its agents and assistants, in making important discoveries in connection with the propagation of the oyster, which are referred to hereafter in this Report; and it is proposed to establish several experimental stations for applying the discoveries thus made, so as to constitute a school of instruction and information to persons practically engaged in the business.

There are other shell-fish besides the oyster that will well repay the trouble of transplantation and multiplication. Among these are several species of clams belonging to the Pacific coast of the United States, which are much superior in size, in tenderness, and in excellence of flavour to those on the eastern coast. Most of these are natives of Puget Sound, and the completion of the Northern Pacific Railway is looked forward to as a convenient means of transferring them to Eastern waters. The common clams of the Atlantic coast are also fair subjects of experiment.

VOLCANIC DUST FROM NEW ZEALAND

A SHORT time since, Sir Julius von Haast sent me a small packet of volcanic dust from New Zealand, and requested me to examine it. The dust fell on June 10 of the present year (the day of the Tarawera eruption) at Matakava, Hicks Bay, 115 miles from the scene of the eruption. This dust is very fine, and, when regarded in the mass, is a dull, darkish gray colour. When examined under the microscope, it may be divided into—

(*a*) Bits of a more or less scoriaceous aspect—tiny lapilli, commonly almost opaque, being only translucent on thin edges—consisting of a somewhat brownish glass containing much disseminated ferrite. With reflected light they are a light to a darkish gray in colour, sometimes slightly reddish or brownish, with moderately rough surfaces. In size they usually vary from about ·005 to ·008 inch in the longest diameter; the former being the more common measurement; the latter is but rarely exceeded, the largest fragment in the portion which I have examined being ·012 inch in diameter; lapilli also occur of less than ·005 inch.

(*b*) Chips, more or less transparent, generally not exceeding ·005 inch in diameter, and of all dimensions downwards to the finest dust. The majority of these chips are glass, commonly quite colourless; some of them contain bubbles, spherical, spheroidal, or more or less cylindrical. Sometimes these are quite ·001 inch in longest diameter. Many chips show a ridgy surface, and are evidently formed by the destruction of a very frothy pumice like that of Krakatão. Some of the glass is of a light brown colour; occasionally it contains microliths of feldspar or trichites. The mineral chips are much less numerous than those of glass; the great majority of them are feldspar. Many of these are flat flakes apparently detached from a basal plane, but a few exhibit twinning. Some may be sanidine, but a plagioclastic feldspar is certainly present. The chips, however, are ill-suited for optical measurements, and the results which I have obtained are rather discordant. So far as I can come to a conclusion, I should say that the extinction-angles seem to indicate the not unfrequent presence of a feldspar which belongs rather to the oligoclase-albite group than to the labradorite-anorthite. I find very few indications of the presence of a pyroxenic constituent. One or two fragments are a greenish hornblende; three or four in general appearance resemble small flakes of magnesia-iron mica—lying on their basal faces, but some of these show dichroism, and only extinguish in certain positions between crossed Nicols, so that they cannot be this mineral. As to their true nature I have not yet been able to decide; however, I think it probable some of the brown flakes are mica.

The result of my examination leads me to conclude that the dust is formed of material which was a glass wherein a porphyritic structure, on a large or a minute scale, was inconspicuous. This Matakava dust appears to agree generally with, though it differs varietally from, that described by Prof. Joly in NATURE (vol. xxxiv. p. 595), the main difference being that the biotite, which seems rather common in his samples, is rare in, if not absent from, the present one. I have not noticed sulphur, pyrite, or magnetite in a recognisable form.

It may be interesting to compare this dust with some samples projected from Cotopaxi, and described by myself (*Proc. Roy. Soc.* No. 231). These specimens came from various distances, ranging from twenty to sixty-five miles from the volcano. That which fell on the summit of Chimborazo (the most distant locality) consists of lapilli and chips; the majority of the grains range from about ·001 to ·003 inch; a very few only attain to a diameter of ·01 inch, and this is barely exceeded. In this dust, however, the lapilli are comparatively rare, the chips of glass and mineral dominating, with a fair proportion of the latter. A reference to the above paper will show the difference between this ash, that from Krakatão, and the above-described from New Zealand. This may be explained by the fact that a porphyritic structure is common in the lavas of Cotopaxi (as in the other summits of the district).

T. G. BONNEY

NOTES

WE have to record the death of General John Theophilus Beaulieu, F.R.S., at the age of eighty-one years. He entered the Indian Army in 1820 as a lieutenant in the Bengal Engineers, and was for some time Superintending Engineer in the Public Works Department for the N.W. Provinces. Among other services to science and to India, General Beaulieu inaugurated the system of magnetic observations in India, and was the author of a book of logarithms of wide reputation. General Beaulieu was elected a Fellow of the Royal Society fifty years ago, and has served on its Council.

THE death is announced, at Berlin, of Dr. A. Fischer, so long resident at Zanzibar, and who has done so much for the exploration of the Kilimanjaro region.

M. CHANCOURTOIS, General Inspector of Mines in France, author of several works on geology, and Professor in the School of Mines, has died suddenly at Paris at the age of sixty-seven.

THE following are the probable arrangements for the meetings of the Society of Arts before Christmas:—"November 24, William Anderson, M.Inst.C.E., "Purification of Water by Agitation with Iron and by Sand Filtration." December 1, adjourned discussion on the paper by Dr. C. Meymott Tidy, on "Sewage Disposal" (read April 14, 1886). December 8, Major-General C. E. Webber, R.E., C.B., "Glow-Lamps, their Use and Manufacture." December 15, J. B. Marsh, "Cameo-cutting as an Occupation." There will be five courses of Cantor Lectures during the session:—(1) "Principles and Practice of Ornamental Design," by Lewis Foreman Day. (2) "Diseases of Plants, with special reference to Agriculture and Forestry," by T. L. W. Thudichum, M.D. (3) "Building Materials," by W. Y. Dent, F.C.S., F.I.C. (4) "Machines for Testing Materials, especially Iron and Steel," by Prof. W. C. Unwin. (5) "The Structure of Textile Fibres," by Dr. Frederick H. Bowman, F.L.S., F.G.S. Two Juvenile Lectures on "Soap Bubbles," by A. W. Reinold, F.R.S., will be given on Wednesday evenings, January 5 and 12, 1887. The meetings of the Colonial Section and of the Indian Section will not commence till after Christmas.

THE General Committee of the Society for the Prevention of Hydrophobia and Reform of the Dog Laws held its fourth meeting on Friday last at the offices, 50, Leicester Square, London, W.C., to consider a programme which had been drafted by a sub-committee and circulated among members and supporters. Mr. Victor Horsley, B.S., F.R.S., Secretary to the Commission on Hydrophobia, attended this meeting by invitation, and was unanimously elected a Member of Committee. Many letters were read expressing approval of the programme and regretting that the writers were unable to attend. Among the gentlemen who thus wrote were Dr. Drysdale, Prof. Fleming, Dr. Norman Kerr, Prof. E. Ray Lankester, Mr. Arthur Nicols, and Prof. Pritchard. The Honorary Secretary having made a financial statement of a satisfactory nature, the Chairman, Colonel R. H. Rosser, briefly explained the care and time given by the sub-committee to the programme, which was then discussed in detail, and ordered to be printed with some additions and alterations.

IT is intended, in Section III. of the Manchester Jubilee Exhibition, to exhibit the historical and modern methods adopted in the several branches of electro-metallurgy, such as gold, silver, platinum, nickel and copper plating, the purification of metals by electrolysis, and generally to illustrate the connection between electricity and chemistry.

INFORMATION has been received by the Board of Trade respecting the oyster fisheries of the Isle of Wight. The oyster grounds and breeding ponds of the Isle of Wight are as follows: —(1) Medina River; (2) Brading Harbour; (3) Newtown; (4) Fishhouse or Fishbourne. In 1867 the Isle of Wight Oyster Fishery Company was started, having the Medina River and Newtown Creek for its grounds. This oyster fishery is said to have done well until 1871, when it was troubled by refuse and sewage discharged by mills at Newport, and a large quantity of the broods were destroyed. The Medina fishery is now for sale. About the year 1873 Major Boyle started a system for breeding oysters at Brading, but in 1876 the harbour works were commenced, and Major Boyle had to relinquish his ponds. The Harbour Board, however, still carry on the oyster breeding at Brading. They have six or seven ponds near St. Helens, which are estimated to contain five or six millions of oysters at the present time. As Brading is not suitable for fattening, the young oysters are sold to various growers to be laid down for one or two years to render them fit for food. Newtown Creek is the best fattening ground in the Isle of Wight, but the fishery company is now in liquidation through want of funds, and the business is in abeyance. At Fishhouse there has been a good fall of spat this last summer, but the ground is much disturbed by barges, which prevents the fishery from being fully developed. The oyster fishery is consequently not very prosperous. The creek, it may be mentioned, was recently cleared, and some sixty or seventy thousand oysters were transferred to Newtown to fatten in a pond placed at their disposal by the Newtown Company. Besides the oyster fishery companies above referred to, there are several fishermen who dredge for oysters at sea in the Solent, and particularly in Osborne Bay. The oysters dredged up are seldom fit for the market, and have usually been sold to one of the companies to be laid down and fattened.

IN Dr. B. W. Richardson's recent Cantor Lectures on "Animal Mechanics," speaking of the mechanism of the heart, he described the number of the pulsations of the heart in different animals—in fish, frog, bird, rabbit, cat, dog, sheep, horse—and made a few comments on the remarkable slowness of the heart —40 strokes per minute—in the horse. Then the number of pulsations in man at various periods of life, and at different levels, from the level of the sea up to 4000 feet above sea-level, was brought under review, and was followed by a computation of the average work performed by the heart in a healthy adult man. The work was traced out by the minute, the hour, and the day, and was shown to equal the feat of raising 5 tons 4 cwt. one foot per hour, or 125 tons in twenty-four hours. The excess of this work under alcohol in varying quantities formed a corollary to the history of the work of the heart, Parkes's calculation showing an excess of 24 foot-tons from the imbibition of eight fluid ounces of alcohol. The facts relating to the work of the heart by the weight of work accomplished was supplemented by a new calculation, in which the course of calculation was explained by mileage. Presuming that the blood was thrown out of the heart at each pulsation in the proportion of 69 strokes per minute, and at the assumed force of 9 feet, the mileage of the blood through the body might be taken at 207 yards per minute, 7 miles per hour, 168 miles per day, 61,320 miles per year, or 5,150,880 miles in a lifetime of eighty-four years. The number of *beats* of the heart in the same long life would reach the grand total of 2,869,776,000.

A METEOR of unusual splendour was seen from the Oxford Road, Banbury, on Tuesday, November 2, at about 8.5 p.m. The fall became visible at about mid-distance between zenith and horizon in a direction west by north. At first the meteor burned with a faint, apparently reddish, light, but when a third of its path had been passed, it burst into an intense blue flame, and, increasing in brilliancy during the next third of its course, it finally died away before reaching the horizon, leaving behind it a long red trail distinguishable for several seconds afterwards. The fall was at an angle of 60°, and during the middle third of the flight the flame was of such intensity as to light up the surrounding country.

REFERRING to a paper at the Paris Geographical Society by Dr. Hamy on "The Interpretation of one of the Monuments at Copan, Honduras," in which an inference is drawn as to early Chinese intercourse with America, Dr. W. H. Dall, writing to *Science*, states his belief that the very wide hypothesis thus broached, and which in one form or another has had a certain currency for more than a century, rests upon a totally insufficient foundation. That wrecked Japanese, and possibly Chinese, from time to time were cast on the shores of America, is beyond question. But there is every reason to believe that the wrecked people were (1) nearly always males, and incapable of colonising; (2) were either killed or enslaved by the Americans in accordance with a general usage; and (3) that neither in arts nor language have they left any appreciable trace on American anthropology. "The statement of Brooks, that the Japanese and Aleuts could communicate without an interpreter, is true to this extent. I was present when the aforesaid Japanese, three males, were brought to the port of Unalashka, and took pains to inquire into the assertion which was made to me at the time. I found that the communications were wholly by signs, and not by spoken language, as the Aleuts could not understand a word of Japanese without its accompanying signs. Secondly, Brooks, who was long Consul in Japan, informed me that he had particularly searched into the matter of the voyage to Fu-sang, and that he had conclusive evidence that the voyage which actually took place was to the well-known and still existing province of Fu-sang in Korea (see Griffis' work), and had no connection whatever with America. Lastly, the mere presence of two simple curved lines on a circular stone, taken by itself, proves nothing as to their meaning, and still less that they had any connection with the Chinese symbol." Dr. Dall concludes by stating that such unbridled hypotheses are the "curse of anthropology."

WE have received a fresh instalment of the very valuable work emanating from the firm of Eduard Trewendt, Breslau, the now well-known "Encyclopædia of Natural Sciences," namely, Nos. 48 and 49 of the first part, and 37 and 38 of the second part. These four numbers deal with three different branches of science. No. 48 of the first part is botanical, a continuation of Drude's masterly work, "Systematic and Geographical Arrangement of the Phanerogams," copiously illustrated with woodcuts, as was the earlier portion of the same publication. No. 49 of the "Alphabetical Manual of Zoology, Anthropology, and Ethnology," takes the reader from "Landschaf" to "Lithodina." Of the abundant material embraced in this compass may be particularly mentioned "Landschnecken," by E. von Martens; "Larven," by Dr. Griesbach; two especially interesting contributions, "Larynx," by von Mojsisovics, and "La Tène-Zeit," by Mehlis; treatises by Jaeger on "Life, and its Conditions, Phenomena, and Stimulations, &c.," as also "Linsen," and "Lippen," by Dewitz. Nos. 18 and 19 of the second part belong to the "Alphabetical Manual of Chemistry," containing the papers—Furfurangruppe (conclusion), Gährung, Galle, Gallium, Gehirn, Gerberei, Gerbsäuren or Gerbstoffe, Germanium, Glas, Glycerin, Glycidsäuren, Glycocoll, Glycoside. As of most general interest in this list of articles may be specially cited "Glycoside," by Prof. Oskar Jacobsen, of which the firm is preparing a separate impression; as also "Gährung," by Tollens; and "Glas," by Engler. The newly-discovered "Germanium" is treated by the editor, Herr Ladenburg himself. In Prof. Liebrich's contribution, "Gehirn," we have a valuable paper on this subject by a recognised authority.

TWO remarkable specimens of deformed fish were taken from a rearing-pond at Delaford this week, and brought to the South Kensington Aquarium. One is a trout about three years old, whose tail is bent to such an extreme that it stands at right angles with the body of the fish. Its mode of progress is laboured, and its appearance is very peculiar. The other specimen is an ordinary stickleback, measuring 4 inches in length, whose body is swollen through dropsy to the extent of 1 inch in diameter. At first sight its appearance is similar to a young mouse, and it requires close inspection to grasp the fact that it is a fish. It moves very slowly, with great expenditure of force, the weight of the contorted body being considerable.

THERE has been a great demand for the German carp lately imported into this country by the Marquess of Exeter and others for the purpose of acclimatisation in this country, and a numerously expressed desire to stock waters that are useless for the purpose of maintaining other fish than carp has been made for the German species.

THE operations in connection with the new Observatory and Marine Fish-Culture Station at Lochbuie, Isle of Mull, to be established under the auspices of the National Fish-Culture Association, are to be commenced forthwith. At a meeting of the Council, held last week, it was arranged to form ponds for the propagation of lobsters, and to make certain observations upon marine fauna. The details of the scheme were placed in the hands of a special scientific committee.

WE have received from Messrs. Horne, Thornthwaite, and Wood, opticians, a map of the moon, 12 inches in diameter, mounted on good stout cardboard, represented as she appears when viewed through a telescope with an astronomical eye-piece. This will be a very useful companion and guide for those amateurs who are studying the lunar surface; it can be conveniently held in the hand while observations are being made. About 300 craters and walled plains are marked very clearly, and the names of the different seas are given in larger letters. At the back is added a short description of some of the chief features.

A SHOCK of earthquake was felt in the district of Beira Alta on the 11th inst.

THE additions to the Zoological Society's Gardens during the past week include a Patas Monkey (*Cercopithecus patas*), from West Africa, presented by Mr. Thomas Baily; a Yellow Baboon (*Cynocephalus babouin*), from West Africa, presented by Capt. J. Henderson Smith, R.A.; two Goshawks (*Astur palumbarius*), European, presented by the Baron d'Epremesnil; a Hobby (*Falco subbuteo*), caught in the Indian Ocean, presented by Dr. Rivis Mead; two Java Sparrows (*Padda oryzivora*) from Java, four St. Helena Seed-Eaters (*Crithagra butyracea*), from South Africa, presented by Mrs. Conrad Pile; two Sing-sing Antelopes (*Cobus sing-sing* ♂ ♀), from West Africa, received in exchange; a Woodcock (*Scolopax rusticula*), European, purchased; an Ocelot (*Felis pardalis*) from America, a Bactrian Camel (*Camelus bactrianus* ♀) from Central Asia, two White-backed Piping Crows (*Gymnorhina leuconota*) from South Australia; a Banded Parrakeet (*Palæornis fasciatus* ♂), from India, deposited; a Vinaceous Turtle Dove (*Turtus vinaceus*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

THE INFLUENCE OF ASTIGMATISM IN THE EYE ON ASTRONOMICAL OBSERVATIONS.—Prof. Seeliger has published, in the *Abhandlungen der k. bayer Akademie der Wiss.*, ii. Cl., xv. Bd., 3 Abth., an interesting paper on this subject. The paper is divided into four sections. The first part treats of certain details connected with the refraction of light which are used in the subsequent investigations. The second part gives the theory of the formation of images in an astigmatic eye, and its application to measures made with an altitude instrument. In the third and fourth parts the author treats of the application of his theory to the heliometer and wire-micrometer respectively. It appears, from Prof. Seeliger's researches, that this malformation in the eye, which is far from uncommon, exerts a larger influence on astronomical measurements than is commonly supposed. Thus, he shows that a systematic error in a series of observed declinations amounting to 0″·26 may very well be due to it. And it appears that the discordances in observed position-angles of double stars, depending on the inclination of the line joining the components to the vertical, with which the measures of some observers are affected, may in part be referred to the same cause. Prof. Seeliger's paper is one which may be profitably studied by those who aspire to the attainment of greater accuracy in astronomical observations.

THE KALOCSA OBSERVATORY.—Dr. C. Braun has recently published a report of this Observatory, founded by Cardinal Haynald, Archbishop of Kalocsa. The equipment of the Observatory consists of a refractor, by Merz, of 7 inches aperture; another of 4 inches; a transit by Cooke, aperture 2·3 inches; an altazimuth by Breithaupt, of Cassel; a chronograph, three clocks, and a chronometer; several spectroscopes, of which a large solar spectroscope with automatic adjustment to minimum deviation is the principal; a star photometer by Zöllner, and a spectro photometer by Vogel and Glan. The two most important works effected at the Observatory have been the determination of the geographical position of the Observatory, and the observation of sunspots. A special value attaches to the former, as hitherto the position of no place in Hungary had been fixed by direct astronomical methods. The latitude of the standard pillar of the Observatory was determined by geodetic observations to be 46° 31′ 41″·92; the astronomical methods made it 0″·07 greater. The longitude was found to be 1h. 15m. 54·343s. east of Greenwich. The observations of sunspots extend from May 14, 1880, to January 31, 1884, and form a useful record of an interesting period. The method of projection was employed in observing; the observations were reduced first by means of a projection of the sun, and secondly by calculation. In the latter method Dr. Braun employed an instrument of his own device, which he terms a trigonometer, for the direct solution of spherical triangles. From his observations Dr. Braun deduces the following expression for the velocity of rotation:—$865°·33 - 209°·86 \sin^2 \lambda$. He also shows the downward tendency in latitude of the mean spotted area, and points out the curious partial effort at recovery which shows itself at tolerably regular intervals. The observations of each rotation are grouped together and given in short tables, and diagrams similar to Carrington's, showing the spots of each rotation in shape and position, are also added. The volume concludes with full descriptions of a number of ingenious instrumental devices, some actually employed at Kalocsa, others still only projected. Amongst these is an ingenious transit micrometer for eliminating personal equation in the observation of transits.

ζ CASSIOPEIÆ.—The *Sidereal Messenger* reports, on the authority of Prof. Colbert of Chicago, that this star appeared to increase its brilliancy by quite half a magnitude on the night of August 20. The most remarkable point of the observation was the shortness of duration of the phenomenon: for, about half an hour after it was first noticed, the star began to return to its normal magnitude. It will be interesting to learn if the change was observed elsewhere.

NEW MINOR PLANETS.—Prof. Peters discovered a new minor planet, No. 261, on October 31, and Herr Palisa two—Nos. 262 and 263—on November 3.

COMET FINLAY.—The following ephemeris for Berlin midnight is in continuation of that given in NATURE for November 4 (p. 17):—

1886	R.A. h. m. s.	Decl. ° ′	log r	log Δ
Nov. 16	19 59 51	23 22·7 S.	0·0697	0·0899
18	20 8 42	22 53·7		
20	20 17 38	22 22·4	0·0689	0·0874
22	20 26 37	21 48·8		
24	20 35 39	21 13·0 S.	0·0693	0·0856

COMET BARNARD.—The following ephemeris for Berlin midnight is given by Dr. E. Lamp (*Astr. Nachr.*, No. 2753):—

1886	R.A. h. m. s.	Decl. ° ′	log r	log Δ	Brightness
Nov. 18	13 16 59	13 12·4 N.	9·9433	0·0637	10·8
20	13 31 51	14 5·9	9·9306	0·0485	12·3
22	13 47 57	14 58·3	9·9180	0·0340	13·9
24	14 5 20	15 47·7	9·9055	0·0207	15·7
26	14 24 2	16 32·5	9·8934	0·0089	17·5
28	14 43 57	17 10·3	9·8817	9·9990	19·3

The brightness at the time of discovery is taken as unity.

GOULD'S "ASTRONOMICAL JOURNAL."—The first number of the new issue of this journal appeared on November 2. It contains the following papers:—On the light-variations of Sawyer's variable in Vulpecula, by S. C. Chandler, Jun., in which the elements of the star are given as Max. = 1885 Nov. 2d. 20h. 35m. G.M.T + (4d. 10h. 29·0m.) E. The minimum is 1·060d. earlier. The rapidity of the rise is a striking characteristic of this star.—A new short-period variable, by E. F. Sawyer. The star, 57 Sagittarii, has a period of not more than 6 days; the variation is from 5·6 mag. to 6·6. Place for 1875·0, R.A. 18h. 14m. 2s.; Decl. 18° 54′ S.—Elements and ephemerides and observations of Comets Finlay and Barnard, by Profs. Winlock, Boss, and Frisby.—Observations of U Ophiuchi, by E. F. Sawyer; and the first part of a paper on the lunar theory, by Prof. Stockwell.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 *NOVEMBER* 21–27

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on November 21

Sun rises, 7h. 31m.; souths, 11h. 46m. 3·1s.; sets, 16h. 1m.; decl. on meridian, 19° 58′ S.: Sidereal Time at Sunset, 20h. 3m.

Moon (New on November 25) rises, 1h. 37m.; souths, 8h. 4m.; sets, 14h. 18m.; decl. on meridian, 1° 57′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	9 30	13 11	16 52	25 2 S.
Venus	7 12	11 35	15 58	18 46 S.
Mars	10 33	14 18	18 3	24 32 S.
Jupiter	4 15	9 34	14 53	8 45 S.
Saturn	19 34*	3 36	11 38	21 22 N.

* Indicates that the rising is that of the preceding evening.

Occultations of Stars by the Moon (visible at Greenwich)

Nov.	Star	Mag.	Disap.	Reap.	Corresponding angles from vertex to right for inverted image	
			h. m.	h. m.	°	°
22	46 Virginis	6	4 42	5 31	72	176
22	*k* Virginis	6	4 58	near approach	304	—
22	48 Virginis	6	6 36	7 8	104	163
23	B.A.C. 4647	6	4 42	5 40	24	222

Nov.	h.	
23	1	Jupiter in conjunction with and 3° 0′ south of the Moon.
23	14	Mercury stationary.

Variable Stars

Star	R.A.	Decl.		
	h. m.	° ′		h. m.
U Cephei	0 52·2	81 16 N.	Nov. 28,	2 27 *m*
ζ Geminorum	6 57·4	20 44 N.	,, 23,	21 30 *M*
S Canis Minoris	7 26·5	8 34 N.	,, 24,	*M*
S Sagittarii	19 12·8	19 14 S.	,, 21,	*M*
η Aquilæ	19 46·7	0 43 N.	,, 24,	0 0 *M*

M signifies maximum; *m* minimum.

Meteor Showers

The *Andromedes*, maximum November 27, R.A. 24°, Decl. 44° N., form the most interesting shower of the week. A radiant near μ Persei, R.A. 60°, Decl. 49° N., supplies very swift meteors; swift meteors are likewise seen from a radiant near η Ursæ Majoris, R.A. 208°, Decl. 43° N.

GEOGRAPHICAL NOTES

THE *Bulletin* of the Paris Geographical Society for the present year (Nos. 1 and 2) contain several papers of interest. We need do no more than mention M. Ch. Mannoir's annual report on the progress of geography during the past year, which fills 130 pages. M. Grandidier writes on the rivers and lagoons of part of the east coast of Madagascar, and M. Gouin, of Nam-dinh, contributes a long paper on Tonquin, which deals with the commercial geography of the country rather than with the geography proper. No. 2 opens with the report of a strong Committee of the Society on the orthography of geographical names, which will be read with interest. No elaborate or exhaustive reforms are proposed; the suggestions are rather a series of simple modifications "based on good sense rather than on high philological science, which is only accessible to the few initiated." The Committee take up the programme of the Royal Geographical Society, "completing it in some respects, and making some additions sensible to musical ears." The bases of the proposals are the same as those of our own Society: (1) not to seek an absolute perfection in the representation of sounds; (2) to preserve in European names the form of the country of their origin; (3) to retain in the case of other places the mode commonly employed. M. Rolland contributes a long paper on the hydrography and orography of the Algerian Sahara; and M. Marteil examines the map of the French establishments on the Senegal recently issued by the Ministry of Marine. Lieut. Baudens describes a trip which he made last year along the Black River of Tonquin; and finally there is an account written by Dr. Potagos in 1880 of a journey which he made in the Pamir in 1870, including a visit to the famous Yakub Beg of Kashgar.

WE have received the *Verhandlungen* (Bd. xiii. No. 8) and the *Zeitschrift* (Bd. xxi. Nos. 4 and 5) of the Geographical Society of Berlin. The first contains only one paper, but that an interesting one, by Dr. Sievers, on a recent journey in the Sierra Nevada de Santa Marta, in Columbia. The object of the journey was to study the geology and physical geography of the region, and especially to ascertain whether these mountains belong to the system of the Andes or not. As Dr. Sievers has only been back for a short time, he was unable to give any definite results, and he confines himself to describing the course of the journey, and to mentioning important points necessary for a proper understanding of the physical geography of the region. In the *Zeitschrift*, Herr Jung continues and concludes his analysis of the Indian census of 1881; this is followed by a translation, from the *Proceedings* of the Russian Geographical Society, of Dr. Iwanow's paper on certain ancient monuments discovered by him in the course of a geological examination of Turkestan. Prof. Gelcich has a highly technical history of the methods of ascertaining the area of a country, and Dr. von Danckelmann one on the frequency of rain in the Indian Ocean. Herr Sandler makes a contribution to the history of cartography by giving an account of the life and works of Johann Baptista Homann, a geographer of the latter part of the seventeenth century. A curious map appended to this paper (which is of considerable length) shows, by means of white and red outlines, the world according to present cartography and according to Homann's maps. The number concludes with a short paper on the hot springs of Kamchatka.

IN a recent work on the geology and geography of Sumatra, M. Verbeek, a Dutch engineer, says that sixty-seven volcanoes are known to exist on that island. There may be more even than this, for parts of the north-west, which are covered with primæval forests, have never been penetrated. Two only of these are active, Merapi and Talang (or Soclau), the former being 2892, and the latter 2542 metres in height.

THE October issue of the *Bollettino* of the Italian Geographical Society contains an account of an excursion made during the summer by E. Modigliani to the rarely visited island of Nias, which lies some thirty miles from the west coast of Sumatra, a little north of the equator. The explorer spent two months in the place, but owing to local feuds was unable to penetrate beyond Fadoro, a large village near Telok Dalam Bay on the south side. The natives, apparently of Malayan or Indonesian stock, but speaking a language quite different from Malay, and by Crawfurd described as "a simple, mild, and primitive people," he found on the contrary to be fierce and treacherous savages, everywhere addicted to head-hunting. Their hostility was such, that he failed to make any botanical or zoological collections; but fortunately secured eleven human skulls from the southern districts, which have been sent to the Anthropological Museum of Florence. No similar specimens appear to have hitherto reached Europe, nor are any found even in the Batavian collection. Head-hunting is taken so much as a matter of course, that on Sig. Modigliani offering to purchase some skulls, the rajah of Bavolovalani on the south coast quietly remarked that it would be rather an expensive business, as an expedition would have to be specially fitted out and sent to the hills to raid upon some neighbouring tribes and carry off the required number of heads. He had no idea of craniological specimens being collected except from the living subject. The interior of Nias still presents a promising field of exploration, never having been visited by any European travellers.

LIGHTHOUSE ILLUMINANTS[1]

II.

V.—*Range of Lights in Hazy Weather*

THE observations on this subject of the Trinity House Committee have served to confirm the conclusions announced by M. Allard in his "Mémoire sur l'intensité et la portée des phares," 1876, and in his more recent "Notes sur quelques objections relatives à l'emploi de la lumière électrique dans les phares." The Committee find that the gas and oil lights which are equal in clear weather are equal also in fogs; that in rather dense fog the more powerful light had but little advantage over the less powerful, for example, "the triform electric appearing at 1500 feet, while the quadriform gas and triform oil showed up together a little before the observers reached 1400 feet," and that the electric light, while suffering, according to the photometric results, a somewhat greater loss in hazy weather than the flame lights, is "visible at a greater distance than the highest powers tried in gas or oil." Using M. Allard's formula, which appears to rest on well-established physical and physiological data, I have calculated the range in fogs of various degrees of thickness of some of the lights exhibited at the South Foreland. The range of a light, or the limit at which it is just lost or just picked up, is that limit at which its intensity is diminished by distance and haze to the minimum intensity perceptible by a good eye, such as the practised eyes of seamen are. M. Allard gives this minimum intensity, on the authority, of "des expériences qui ont été faites sur ce sujet au Champ de Mars," as that of 1/100 Carcel at a distance of one kilometre on a perfectly clear night. This corresponds to ⅓ candle at a distance of one nautical mile. When the air is not perfectly clear,

[1] Further Report of Mr. Vernon Harcourt to the Board of Trade on the Experimental Lights exhibited at the South Foreland. Continued from p. 46.

its degree of transparency may be expressed by stating the fraction of light which escapes obstruction in passing through a certain length. Of this fraction the same fraction escapes obstruction in passing through another equal length of air, and so forth. Thus, if this fraction is called a, and l is the intensity at any point of a beam of parallel rays, such as a beam of sunlight reflected from a plane mirror, after the beam has traversed a mile of hazy air its intensity is diminished to la, at two miles its intensity is diminished to la^2, and at a distance of d miles to la^d. But divergent light, such as is even the most condensed beam from a lighthouse, diminishes also as the square of the distance. Thus, if L is a lighthouse light whose intensity at one mile is La, its intensity at any number of miles, d, is $La^d \times \frac{1}{d^2}$; and when the combined effect of haze and distance is such that its intensity is only equal to that of ⅓ candle at one mile, at that point the light ceases to be visible. Thus it is possible to calculate for any particular degree of haze what will be the range of any given light. To give some examples:—In a moderate uniform haze such that a single 108-jet gas-burner, showing as a fixed light of about 14,000 candles, was lost at a distance of 10·9 miles, the same light shown in biform would be lost at 11·8 miles, while the corresponding triform and quadriform lights would be lost at 12·5 and 12·8 miles respectively. In a rather thicker haze, in which a single 108-jet gas-burner, showing as a revolving light of 60,000 candles, was visible up to 10 miles, but no further, the extreme range of the biform would be 10·73 miles, of the triform 11·16 miles, of the quadriform 11·48 miles. In still thicker haze the increase of range obtained by increasing the power of the lighthouse light becomes not only absolutely but relatively less.

Light shown	Range in Nautical Miles		
Single 108-jet, M. I. lens	2	1	0·5
Biform ,, ,,	2·11	1·05	0·52
Triform ,, ,,	2·17	1·08	0·54
Quadriform ,, ,,	2·22	1·1	0·55

The above results represent the maximum range of the direct beam through uniform haze of lights of the same kind but varying in power. But in certain cases the increase of range gained by increasing the power of the light may be either less or greater than it is in the foregoing case.

In the first place, the light which has suffered obstruction is diverted from its direct course but is not lost; and a portion of this light may reach the eye from a direction slightly different from that of the source of light, producing the impression of a halo or burr. Prof. Stokes, Pres. R.S., who has kindly given me much help in considering this subject, concludes that, especially in a fog in which the particles of water are not very minute, the burr might be seen at a substantially greater distance than that at which the direct light could be seen. "The intensity of this diffused light will not decrease in geometric progression as the distance from the source increases, but rather will tend ultimately to decrease inversely as the square of the distance; but being so widely spread, there will be danger of its being unperceived unless it be flashy." In this case the more powerful lights would retain in fog more nearly the advantage which they possess in clear weather, in which a fourfold light has double the range of a single light. But since the eye can distinguish between the point of light which is seen by the direct rays and the blurred nimbus, whose properties Prof. Stokes has investigated, the question whether the range of powerful lights is materially increased by the diverted and re-diverted light which surrounds the principal beam could be solved by an appeal to experience.

In answer to my inquiry whether it often happens that in approaching a lighthouse on a hazy night that which is first seen is an indistinct brightness or halo, not the light itself, and whether this effect is seen at considerable distances or only at short distances, and in what kind of fog, the Deputy Master of the Trinity House tells me that it happens, occasionally, at short ranges, in thick fog or mist, when nothing of the light is seen beyond 1 or 2 miles. "In clearer weather (*i.e.*, slight haze) this peculiarity is not observable at any range; it is the direct beam from the lantern (of course lessened and indistinct by reason of the density of the atmosphere) which then comes to the eye of the observer when approaching from seaward." I think, therefore, it may be concluded that at short distances powerful lights may occasionally have an advantage over feebler lights greater than is indicated by M. Allard's formula, in consequence of the scattered light being less diminished by fog than the direct light.

There are two other cases in which the formula is not immediately applicable; the second exception being, if the haze is not uniform. This case may be illustrated by taking an extreme example. Suppose that the amount of fog extending 5 miles from a lighthouse were just sufficient to extinguish a light of 60,000 candles, and that beyond this distance the air were perfectly clear, a light of four times the initial power would have at the margin of the fog four times the minimum visible brightness, and would only disappear altogether at a distance of 10 miles. But, on the other hand, if the fog were thicker further to seaward, the larger light would have scarcely any advantage over the smaller light.

Thirdly, if the lights compared differ in quality, of which the visible sign is colour, as well as in power. In this case the particles of water of which haze at sea consists (differing from the coloured particles of a London fog) are only likely to exercise a selective action on lights of different refrangibilities when the particles are so small as to be comparable with a wave of light. In a thick mist, in which the particles of water have often a visible magnitude, this effect is probably absent. Clouds are of this character, and sunlight is not reddened by passing through them. But the red colour of the sun when near the horizon, and the assimilation in colour of the electric light to gas-light when seen from a distance through slight atmospheric haze, shows that such haze does interfere with the more refrangible blue rays, to a greater extent than it does with the yellow, orange, and red rays. It is therefore certain that the electric light, which contains a relatively large proportion of the more refrangible rays, suffers a greater loss than the light from gas or oil flames in certain states of the atmosphere. The larger particles of mist or rain probably obstruct light of all sorts in the same degree. If we suppose that the effect of haze is to cut off all the blue and violet rays, the loss to the flame lights would not exceed 1 or 2 per cent., while that of the electric light, which is perhaps rather bluer than sunlight, may amount to 20 per cent. But this loss, though considerable, would not materially affect the range of the electric light in hazy weather.[1]

It has been claimed as an advantage of multiform lights, compared with the electric arc behind a small lens, that the larger surface of illuminated lens is more favourable to visibility in hazy weather; and the late Sir W. Siemens gave some countenance to this view. Speaking in the discussion of Sir James Douglass's paper "On the electric light applied to lighthouse illumination," 1879, he said:—"He had held that, in order to get more penetrating power, not intensity alone, but intensity with quantity as represented by large surface, would be required." M. Allard in his "Note," pp. 10 and 11, makes some interesting observations on this subject, but deals rather with visibility at great distances in clear weather than with visibility through haze. I do not know on what grounds, either of theory or observation, the opinion formed by Sir W. Siemens is based. Desiring further information on this and some other points, I have consulted Lord Rayleigh, Sec. R.S., who with Prof. Stokes joined me in a visit to the South Foreland lights a year ago. I may quote his opinion:—"With the same total brightness of source, and angle of divergence, it can make no difference at a distance (at which the apparent magnitude of the lens is inappreciable), whether the lens be large or small. At smaller distances the advantage might be with the smaller lens. So far as I see, the only advantage that the large lens could ever have would be more room for a bulky light, which, with a small lens, might give too great a divergence."

While referring to the assistance I have received from Prof. Stokes and Lord Rayleigh, to whom I desire to accord my thanks, I should mention that I have received from both the same emphatic suggestion, that further trial should be made of sudden flashes in fog. Lord Rayleigh writes: "I should like to see proper experiments tried on sudden and periodic flashes, such as might be produced by gunpowder, the periodicity serving for identification and the intermittence being necessary to

[1] Since this report was written, a paper has been communicated to the Royal Society by Captain Abney, R.E., F.R.S., and Major-General Festing, R.E., F.R.S., giving the result of measurements of the illuminating power of different parts of the spectrum of the electric arc. According to these measurements, the illuminating power of that part of the light from the electric arc which lies beyond the line "E" in the spectrum, including the greater part of the green rays as well as the blue and violet rays, is rather less than one-sixth of the total illuminating power.

get the necessary contrast, which is here between appearances at consecutive *times*, instead of as in ordinary vision between appearances in neighbouring *directions*."

Prof. Stokes writes, on various occasions:—"The diffused light of a powerful lamp would be weak and perfectly steady, and might thus escape notice, while a diffused light, even though no stronger, if almost momentary like lightning might be sufficient to attract attention, and you could afford to throw great chemical force into the formation of a flash which was to last only, as it were, for a moment." "If there are to be any more experiments, I think it would be well worth while to try explosions." "The more I think of it the more disposed I am to think that it would be worth while to try some experiments with flashes, I mean with explosions. The plant would not be at all costly; in fact, it would hardly cost anything. The chemicals would not cost very much. Preliminary experiments on a small scale, which could be tried anywhere, would show what chemicals were good to use in order to get a flash as bright as may conveniently be. But when the actual experiments in fog are tried, the quantity used should not be by any means very small. It should be enough to make the quantity of light for the moment much greater than what was kept up in your most powerful burners; but that would not require a very large quantity."

I should add that Prof. Stokes is aware that "flares" have been tried and used, but is clearly of opinion that further trials should be made in that direction. As to the great effect of sudden illumination in attracting attention there can be no doubt; but I find it hard to believe that in a fog in which an observer at a small distance was unconscious when the beam from the electric arc, through such a lens as the Mew Island lenses, passed quickly across him, any "flare" would be perceptible at the same distance. I do not know whether the experiment has been tried of combining a light-and-sound signal, by placing the materials used to produce a flash together with a charge of compressed gun-cotton in the head of a rocket, and so firing the rocket that it would explode at a fixed distance and bearing from the station and at a moderate altitude. A rocket will go through any fog, and might be used to give a lift seaward to the light and sound.

VI.—*Cost of each System*

I have not the data which are necessary for forming an independent opinion upon the estimates furnished in the Trinity House report. These estimates rest on unexceptionable authority; and I only venture to make any remarks on the subject because I am not entirely satisfied with the position assigned to the electric light.

I gather from the reference to the photometric results of Mr. Valentin that in a former estimate the cost was considered in relation to the yield of light by each illuminant. And I think that an estimate of what light can be had on any system for a given expenditure, or what the cost is on any system of a desired quantity of light, is needed to make the comparison of the relative cost complete. For example, a comparison is made in the Report (Tables I. and II., pp. 62–63), between a "first order oil-lighted tower for one six-wick burner only," and a "gas station to show a quadriform light of four times 68-jet power." The annual cost of maintenance, including interest on capital outlay, is estimated at 724*l.* for the first, and 1687*l.* for the second. But the light from a six-wick burner shown as a fixed light is probably rather less than 7000 candles, while that from the 68-jet quadriform is 35,000 candles. Thus, if such a quadriform were substituted for or adopted instead of the single light, both the cost and the light would be largely increased, but the increase of light would be more than double the increase of cost. Comparing the two as revolving lights, the increase of light would be one-third greater than the increase of cost. So in the comparison between the cost of the electric light and the other illuminants. The expense of annual maintenance, with interest on capital outlay, is estimated as being one-seventh greater for the electric light than for the quadriform 68-jet gas; but if the yield of light is taken into account, the figures appear very differently. The electric light is ten times as powerful as the quadriform. The actual cost of light, which is the commodity produced, may be compared in the two cases by stating the cost of maintaining for one year each 1000 candles intensity of light in the beam sent forth. By the electric arc the cost is about 1*l.*, by the quadriform gas 8*l.* 10*s.*

As to the actual estimate of the cost of the electric light, I venture to suggest that some reduction may be found practicable. Two engines of 30 horse-power, at a cost of 1250*l.*, seems a very full provision for the unfailing maintenance of one arc light. The actual horse-power absorbed by one of the De Méritens machines is given by Prof. Adams as 10·4. M. Allard states the price of one of M. de Méritens' machines, tested and recommended by him in 1880, as 350*l.* Dynamo-machines are, I believe, less costly. I think all that is needful and best of machines, lamps, and cables, may now be obtainable for less than 2154*l.*; and the estimate of 1217*l.* a year for wages, clothing, coke, oil, carbons, &c., and repairs and renewals, may perhaps be found in excess of the necessary cost. M. Allard gives the following details of the cost of the apparatus and expenses at Grisnez:—

	£
Two steam-engines of from five to six horse-power ...	488
Two magneto-electric machines	852
Four lamps	240
Total	1580
Annual expenses	537

He also furnishes an estimate, which I transcribe, of the average cost of converting an oil lighthouse into an electric lighthouse:—

	£
Engine-house, keepers' dwellings, water-supply, &c. ...	1600
Two steam engines, of from six to eight horse-power, with shafting and straps	640
Two electric machines with cables, &c.	560
Four lamps	240
First order lantern with oblique framing	800
Optical apparatus, two feet in diameter, with arrangements for revolving light	520
Sundries, packing, carriage, and setting up	240
Contingencies	400
Total	5000

Add "First cost of an ordinary first order oil-lighted tower" (T. H. Report, Part I., p. 75), less "Apparatus, lantern and glass," viz. 4834*l.*; and it would seem to follow that the first cost of an electric light station need not exceed 10,000*l.*

The rather large difference between this estimate and that of 17,749*l.* furnished by the Trinity House Committee has no doubt already received the consideration of the Elder Brethren, who have had the details of M. Allard's scheme before them.

In order to obtain some further information, I have inquired of a London firm of electric light contractors as to the cost of such an installation, and have received the following figures:—

	£
Two 30 horse-power *effective* engines	700
Three lamps, necessary cable, and labour	400
Two dynamos and spare armature to fit either ...	480

It will be seen that these figures are not very different from those of M. Allard's estimate.

In concluding this report I desire to thank the Elder Brethren of the Trinity House, and especially the Members of the Committee, for the kindness which has made the duty of co-operating with them in this inquiry a continual pleasure.

March 9, 1886 A. VERNON HARCOURT

Letter to the Board of Trade from the Commissioners of Northern Lighthouses

Northern Lighthouse Board, 84, *George Street, Edinburgh, December* 10, 1885

SIR,—I am directed by the Commissioners of Northern Lighthouses to acknowledge the receipt of your letter of the 3rd instant, in which you request to know whether the Commissioners propose to make any general report or observations relative to the recent Lighthouse Illuminants Experiments at the South Foreland.

In reply I am directed to state that in view of the very able and exhaustive Report (Part I.) by the Committee of the Elder Brethren on this subject, in the conclusions of which the Commissioners concur, and of the report by their engineers dated October 14 last, which accompanied my letter to the Elder Brethren of the following day, and copy of which is herewith transmitted for the information of the Board of Trade, the

Commissioners do not propose, at least in the meantime, to make any general report or further observations in regard to these experiments.—I am, &c.,

(Signed) J. M. DUNCAN

The Assistant Secretary, Harbour Department,
Board of Trade

Report on Part I. of Report by the Special Committee of the Elder Brethren on Lighthouse Illuminants, by T. and D. Stevenson, Engineers, to the Northern Lighthouse Board

On September 2 last, the Board remitted to us, for consideration and report, Part I. of the Report of the Committee of the Trinity House, on the experiments at South Foreland, and having perused the reports of the experiments, we now beg to report as follows:—

As the Board is aware, the object of these experiments was to determine the relative merits of gas, oil, and electricity, as lighthouse illuminants, especially as regards their penetrative power in fog; also to ascertain the merits of certain optical arrangements, and test certain improved oil and gas burners patented by Sir James Douglass and Mr. Wigham. We think that these experiments embrace all the suggestions that were brought under the notice of the Elder Brethren for trial by the Board of Trade, and which led that Board to suggest that this train of experiments should be entered upon.

We have had several opportunities of inspecting the various kinds of apparatus, and also of witnessing the experiments, and in our opinion these experiments have been of an exhaustive character, and have been conducted with great care, and, we believe, in a spirit of the most perfect fairness and impartiality to all parties; and we have further to express our concurrence in the conclusions of the Committee as expressed in the following terms:—

"(1) That the electric light, as exhibited in the A experimental tower at South Foreland, has proved to be the most powerful light under all conditions of weather, and to have the greatest penetrative power in fog.

"(2) That for all practical purposes the gaslight, as exemplified by Mr. Wigham's multiform system in B experimental tower, and the oil light, as exemplified by the Trinity House Douglass six-wick burners in multiform arrangement up to triform in C experimental tower, when shown through revolving lenses, are equal, light for light, in all conditions of weather; but that quadriform gas is a little better than triform oil.

"(3) That when shown through fixed lenses, as arranged in the experimental towers, the superiority of the superposed gas light is unquestionable. The larger diameter of the gas flames and the lights being much nearer to each other in the gas lantern, give the beam a more compact and intense appearance than that issuing from the more widely separated oil burners.

"(4) That for lighthouse illumination with gas, the Douglass patent gas-burners are much more efficient and economical than the Wigham gas-burners.

"(5) That for the ordinary necessities of lighthouse illumination, mineral oil is the most suitable and economical illuminant, and that for salient headlands, important landfalls, and places where a very powerful light is required, electricity offers the greatest advantages."

We may explain that so far back as 1869 we had also occasion to conduct a series of experiments at Edinburgh on certain large burners patented by Mr. Wigham, and brought before the Board, with the view of increasing the power of sea lights, and again in 1870 a further series of experiments was carried out by us, by the direction of the Board of Trade, on the merits of the electric light, and certain important results were obtained during these sets of experiments at Edinburgh. The general result of the gas experiments then made was that the large 52-jet gas-burner was in no way superior to the 4-wick oil-burners when used in connection with the ordinary annular lens, as the "greater portion of the 7-inch gas flame" was with that size of lens necessarily ex-focal. The large burner was slightly superior, however, when used in a fixed light apparatus. Our opinion, which has been corroborated by the recent experiments, therefore, was that in order to bring out the full power of these large flames, an apparatus of larger focal distance than usual must be employed, and hence we designed the lens of 1,330^{mm} radius, which has recently been tried at the South Foreland with the most satisfactory results.

The electric light experiments made at Edinburgh in 1867–1869, showed that if the electric light beam was made to diverge artificially to the same extent as the 4-wick oil flame, it was in no way superior in brilliancy, and pointed to the advisability of adopting for the electric light the azimuthal condensing system of Mr. Thomas Stevenson. This system has been adopted for the electric light apparatus at the South Foreland experiments. The Edinburgh experiments further showed that it was necessary in any test of the intrinsic merits of electricity, gas, or oil, that the maximum condensation consistent with the requirements of navigation for each should be employed. At the South Foreland experiments, however, the condensation of the electric light was only 30° into 5°, that is only 6 times, whereas the Isle of May apparatus, which was exhibited at the South Foreland, condensed 45° into 3°, that is 15 times. Had this or a still more condensed light been used in the experiments, the electric light would have shown even greater superiority than it did.

We shall afterwards report as to what, in our opinion, is the arrangement of optical apparatus best suited for each illuminant. (Signed) T. and D. STEVENSON

Edinburgh, October 14, 1885

OFFICIAL REPORT ON THE USE OF OIL AT SEA FOR MODIFYING THE EFFECT OF BREAKING WAVES[1]

THE following Memorandum, dated June 16 last, on the use of oil at sea for modifying the effect of breaking waves, has recently been printed and circulated by the Admiralty:—

"Many further practical experiments at sea have been made since the report by Capt. Chetwynd, R.N., to the Royal National Lifeboat Institution, dated September 30, 1884, on the use of oil for smoothing broken or troubled waters, which report was communicated to Commanders-in-Chief in Admiralty Circular Letter of December 1, 1884, N.S. $\frac{3206}{8305}$.

"As these further experiences go to show that the use of oil, under different circumstances, is of very extended and simple application, my Lords Commissioners of the Admiralty consider it desirable, in order that the facts may be generally known, to re-issue the report above mentioned, together with such other information as may serve for the guidance of officers, whose attention is hereby called to the fact that a very small quantity of oil skilfully applied may prevent much damage both to ships (especially the smaller classes) and to boats by modifying the action of breaking seas.

"The principal facts as to the use of oil are as follow:—

"On free waves, *i.e.* waves in deep water, the effect is greatest.

"In a surf, or waves breaking on a bar, where a mass of liquid is in actual motion in shallow water, the effect of the oil is uncertain, as nothing can prevent the larger waves from breaking under such circumstances; but even here it is of some service.

"The heaviest and thickest oils are the most effectual: refined kerosene is of little use; crude petroleum is serviceable when nothing else is obtainable; but all animal and vegetable oils, such as waste oil from the engines, have great effect.

"A small quantity of oil suffices, if applied in such a manner as to spread to windward.

"It is useful in a ship or boat, both when running, or lying-to, or in wearing.

"No experiences are related of its use when hoisting a boat up in a seaway at sea, but it is highly probable that much time and injury to the boat would be saved by its application on such occasions.

"In cold water, the oil being thickened by the lower temperature, and not being able to spread freely, will have its effect much reduced. This will vary with the description of oil used.

"The best method of application in a ship at sea appears to be hanging over the side, in such a manner as to be in the water, small canvas bags capable of holding from one to two gallons of oil, such bags being pricked with a sail needle to facilitate leakage of the oil.

"The position of these bags should vary with the circumstances. Running before the wind, they should be hung on

[1] From the *Board of Trade Journal*.

either bow, *e.g.* from the cathead, and allowed to tow in the water.

"With the wind on the quarter, the effect seems to be less than in any other position, as the oil goes astern while the waves come up on the quarter.

"Lying-to, the weather bow and another position farther aft seem the best places from which to hang the bags, with a sufficient length of line to permit them to draw to windward while the ship drifts.

"Crossing a bar with a flood tide, oil poured overboard and allowed to float in ahead of the boat, which would follow with a bag towing astern, would appear to be the best plan. As before remarked, under these circumstances the effect cannot be so much trusted.

"On a bar with the ebb tide, it would seem to be useless to try oil for the purpose of entering.

"For boarding a wreck, it is recommended to pour oil overboard to windward of her before going alongside. The effect in this case must greatly depend upon the set of the current and the circumstances of the depth of water.

"For a boat riding in bad weather from a sea-anchor, it is recommended to fasten the bag to an endless line rove through a block on the sea-anchor, by which means the oil is diffused well ahead of the boat, and the bag can be readily hauled on board for refilling if necessary."

ON THE INTENSITY OF REFLECTION FROM GLASS AND OTHER SURFACES[1]

THE author pointed out that most previous experimenters, especially Rood, had measured the amount of the transmitted light, and that any percentage of error in this measurement was greatly multiplied when the results were used to calculate the amount of reflected light. In his experiments the amount of reflected light was measured directly. The method was as follows. Light from a cloud was passed through ground glass in the window of a darkened room, and made to fall at the polarising angle on a plate of glass. The transmitted and reflected rays were conducted along different paths by a series of reflectors, but finally emerged side by side and of equal intensity. One of the reflectors in the path of the reflected ray was the glass surface to be tested, the light falling on it at an almost perpendicular incidence. This glass was now removed, and a single mirror was shifted so as to make the angles and points of incidence of the reflected ray on the several mirrors the same as before. The reflected ray was now brighter than the transmitted. To re-establish equality a disk with holes in a ring round the centre was rotated in the path. The ratio of the sum of the breadths of the holes to the whole circumference of the ring gave the percentage of the light that was reflected. For a piece of optically-worked blackened glass the amount reflected was ·058 of the total incident light. It was found that the amount of reflection depended greatly on the clearness and polish of the surface. Thus in one case re-polishing increased the amount from ·04095 to ·0445. Fresnel's formula gave in this case ·04514. Generally it appeared that the amount reflected was less than according to Fresnel's formula—a result contrary to that of Rood's. The numbers for polished glass and for silver on glass were ·94 and ·83.

ON THE NATURE OF SOLUTION[2]

IN connection with the discussion on the "Nature of Solution," in Section B, at the Birmingham meeting of the British Association, the following paper was read by Spencer Umfreville Pickering, Professor of Chemistry at Bedford College:—

The "hydrate" theory attributes dissolution to the existence, in a stable or partially dissociated condition, of definite liquid compounds (generally unknown in the solid form) of the substance dissolved and its solvent, and the mixing of these compounds with excess of the solvent.

In certain special instances we have direct evidence of the reality of such compounds,[3] but it is on general grounds rather than on any special experiments that I would seek to establish their existence.

[1] Abstract of a Paper read at the Birmingham meeting, 1886, of the British Association, by Lord Rayleigh.

[2] Continued from p. 22. From the *Chemical News*

[3] See especially Berthelot, *Ann. Chim. Phys.* (5), 4, 445 to 537.

There is, in the first place, a strong *primâ facie* improbability that substances such as copper sulphate, potassium hydrate, &c., which possess such an intense affinity for water, should be capable of existing in the anhydrous condition in the presence of an unlimited amount of water.

We know, moreover, that in a great number of cases—where a dehydrated salt is placed in water—hydration does undeniably precede dissolution,[1] and in such cases the salt can only exist in the liquid in the uncombined state if the continued action of the solvent is to decompose the hydrate which it has just formed. The only two forces by which such a decomposition might be supposed to be effected are (1) the attraction of the bulk of the water present for the few molecules of water combined with the salt; (2) the attraction of this same bulk of water for the (anhydrous) salt molecules. On the one hand, however, it is absurd to imagine that the mass of water molecules possess such a strong attraction for the few contained in the hydrate as to decompose this latter, or, even if they did, that they would ever have given them up to the salt in the first instance; and, on the other hand, it is equally absurd to urge the intensity of the attraction of the salt molecules for the water molecules as a reason for these two parting company.

Another general fact, which lends considerable support to the view that the dissolution of a salt is due to the formation of a hydrate, is, that those salts which *combine* with water always *dissolve* in that liquid, and, as a rule, the greater the energy with which they do combine with it, the greater is their solubility.

The thermal phenomena attending the act of dissolution point incontestably to the same conclusion. When a dehydrated salt (say $MgSO_4$) is dissolved in water a considerable evolution of heat occurs: and by the simplest experiment it can be established, beyond any possibility of doubt, that all, or the greater portion of this heat is due to the hydration of the salt. If the salt be taken in the hydrated condition less heat is evolved, and, without a single known exception, this evolution diminishes continuously as the salt taken is more and more highly hydrated; but even when taken in its most highly hydrated condition the evolution of heat is in many cases still very considerable.[2] Now, unless we can reconcile ourselves to attribute the heat evolution in this latter case to a cause entirely different from that which exists in the other cases,—unless we are content to shut our eyes to the proportionality between the heat evolved and the degree of hydration of the salt taken,—we must admit that even with a fully hydrated solid salt the heat evolved is due to further hydration; that not only do hydrates exist in solution, but that they are often of a higher order than the highest known in the solid condition.

Coming now to the other side of the question, we find many general considerations, as well as special results, brought forward against the hydrate theory of solution. The latter, however, are for the most part, I consider, urged on mistaken notions, and prove nothing *pro* or *con*.

Thus Dr. Nicol's study of the molecular volumes of salts in solution shows that their volumes are entirely uninfluenced by the presence or absence of water of crystallisation in the solid salt; that if any water is still combined with the salt when dissolved it acts in the same way, and is quite indistinguishable from the rest of the solvent present. In so far as his conclusion that these molecular volumes afford no evidence in support of the existence of combined water, I entirely agree with Dr. Nicol; but in concluding that therefore no water is combined, he has pushed his conclusions far beyond legitimate limits. The same reasoning that leads to the belief that the water and the salt bear no chemical relationship towards each other in solution would hold equally good with reference to the radicles of which the salts themselves are constituted, as Favre and Valson indicated in 1875 (*Comptes Rendus*, lxxv. 1000). Each radicle possesses its own specific volume entirely uninfluenced by the

[1] Dr. Nicol (*Phil. Mag.* 1885, i. 453, and ii. 295) quotes experiments with sodium sulphate in opposition to this view. He shows that the dehydrated salt may dissolve in water under certain circumstances without any signs of previous hydration. When it does so, however, it forms a supersaturated solution, which is certainly very different from a normal solution, being, according to Dr. Nicol's determination of the solubility, due to the extension at lower temperatures of conditions which exist naturally only above 33°: but when it dissolves to form a *normal* solution it is with evident signs of hydration. Whatever this may prove as to the supersaturated solution, it certainly does not prove that the normal solution contains the anhydrous salt, —rather the opposite.

[2] Thus the "true" heat of dissolution of $MgSO_4 7H_2O$ is +7000 cal., and even this number is probably 1000 to 3000 cal. too low, as it contains no allowance for the heat of fusion of the $MgSO_4$ molecule. (See *Chem. Soc. Trans.* 1886, 279.)

nature of the other radicle with which it is combined: the radicles behave independently, and as if there were no combination between them.

Nor is it only from a study of the volumes of salts in the dissolved state that such results are obtained. Numerous determinations of the extent to which the vapour-pressure, the freezing-point, and the temperature of maximum density of water is influenced by the presence of various salts in it, have been made by Wüllner, Blagden, Dufour, Depretz, Rüdorff, and De Coppet,[1] with the general results that certain hydrates of the salt are in some cases present, and in others the salt is anhydrous; but these conclusions, which would tell more against the hydrate theory than for it, are eminently unsatisfactory. The whole question, however, has been re-opened by Raoult (*Ann. Chim. Phys.* (5), 28, 133; (6), 2, 66, 4, 401); and by an exhaustive extension of the work, and by including solvents other than water, and solids other than salts, he has thrown a new light on the subject. Not only does the salt, in its influence on the freezing-point, show no signs of the presence of combined water, but it shows no signs of itself being a single compound; each of the radicles contained in it acts independently of the other, and in precisely the same manner as a *molecule* of a non-saline substance (see especially *loc. cit.* 4, 426). Precisely similar conclusions as to the apparent non-combined state of radicles in a dissolved salt were arrived at by Valson in his work on capillarity (*ibid.* 1870), and by Hugo and Vrié (*ibid.* 1883) in their examination of the effect of membranes on salt-solutions. Other instances of a similar nature, physical and thermo-chemical, might be quoted.

That atoms or molecules which are undoubtedly united may retain their individuality so far as to act towards certain agents as if they were free, is surely not surprising; and from such methods as would lead us to conclude that the very radicles composing a salt are uncombined, it would be useless to look for evidence of the more feeble combination of the salt with its water, and inconsistent to argue, from the absence of such evidence, that no combined water is present.

Although I am not inclined to attribute any weight to these special experiments brought forward against the hydrate theory, it is otherwise with more general considerations.

The formation of hydrates cannot explain the absorption of heat which in many cases accompanies dissolution. The phenomena of solution are too universal to permit of imagining the existence of some definite compound of the dissolved substance with the solvent in every case. There is a continuous influence exerted by the salt on its solvent too extensive to be accounted for by the effect of mass on partially dissociated hydrates; there is a continuity between the fused and dissolved states in many cases, and a regularity in the variation of solubility with change of temperature, &c., which cannot be thoroughly explained on the hydrate theory.

However undeniable the existence of these compounds may be in many cases, they do not give an adequate explanation of all the facts of dissolution.

The hydrate theory can be neither rejected nor accepted.

The explanation of this contradiction is not, I think, very difficult to find. We are talking about molecules of solids and liquids, not as they exist, but as they do *not* exist. Our chemical formulæ for them represent but the results of analysis, or, at the most, the constitution of the substance in that transitory state of simplification which immediately precedes entire decomposition; what their composition may be when in the free state, and removed from all decomposing forces, we know not; all we do know or believe about them is, that they are then far more complex than chemical formulæ represent.

Crystalline form alone would show that a number, probably a very great number, of our so-called molecules combine together, bear certain definite relations and hold certain definite positions towards each other, producing a molecular aggregate or physical unit, which alone should receive the name of molecule.[2]

Just as a number of similar particles unite to form an aggregate or true molecule of any simple substance, so will dissimilar particles unite to form aggregates of a more complex nature.

It is but natural that our prejudices in favour of the "laws" of chemical combination and atomic valency, to which we owe so much, should lead us to attribute the variable composition of certain substances to our imperfect means of investigation rather than to the nonconformity of these substances to our laws. Whether we be right or not in our explanation, we must acknowledge that apparent *in*constancy in composition is one of the most marked features of immense classes of substances which cannot be termed other than chemical compounds.

The varied composition of minerals is said to receive an explanation in the statement that isomorphous substances may displace each other in definite proportions, but to an indefinite extent. This is undoubtedly true, but it does not obviate the necessity of recognising the existence of some form of attraction between these isomorphous substances. No purely mechanical or physical cause can explain this phenomenon; mere similarity of crystalline form has been proved to be incompetent to produce such results. A selective power is exhibited by the substances which thus unite,[1] as well defined as that selective power which in the case of simpler substances has received the name of chemical affinity, and the resulting compounds are characterised by the same uniformity in composition and physical properties[2] which is the attribute of acknowledged chemical compounds.

Nor is it with minerals and artificial crystals only that we find ourselves in what would appear to be a wide border-land between chemical compounds and mixtures. Whether we study the formation of alloys, the occlusion of gases by solids, ranging from the most mechanical action by insensible gradations to the formation of a substance having every appearance of a definite compound, or the decomposition of some of the firmest chemical bodies by so-called mechanical means (filtration), or the constant change in composition of many basic salts with change in the circumstances of their formation,—we are forced to admit that the definiteness which characterises the combination of atoms may be absent from, or at any rate unrecognisable in, the combination of our so-called molecules to form complex aggregates.

When we examine the constituents of these apparently indefinite compounds, it becomes clear that it is only substances which resemble each other which can combine in this manner; and one of the most striking features of dissolution offers such a strict parallel to this, that its meaning can scarcely be mistaken.

A certain degree of similarity in nature between the solvent and the substance dissolved is the invariable accompaniment of dissolution.

Dissolution, I believe, is but one of the many results of apparently indefinite chemical combination.

We cannot obtain a satisfactory explanation of the composition of minerals by admitting the existence of *definite* double salts only, nor can we explain the phenomena of dissolution by confining our attention to *definite* hydrates only. These may, and in all probability do, exist in solution, but they are only small circles within the larger ones; their successive formation and decomposition would give rise to irregularities and effects such as those which are observed in some cases; but these irregularities would form but ripples on the more regular changes which would accompany the variations in the molecular aggregates,—variations which, as in the case of minerals, would be so dependent on physical conditions as to obliterate their chemical nature when examined from many points of view.

The evolution of heat accompanying dissolution will still be attributable, as on the ordinary hydrate theory, to the formation of chemical compounds, but the far greater complexity, and, consequently, instability of these, than of atomic hydrates, if I may so call them, will remove all difficulty in comprehending the continuous effect of the mass of the solvent upon them, even when the latter exceeds that of the salt many hundred-fold; where heat is evolved, therefore, the evolution will be increased, though at a diminishing rate, by dilution.

The rapid increase in the heat of dissolution, produced by a rise of temperature, is but a necessary consequence of the formation of a chemical compound possessing a specific heat less

[1] For a general summary and discussion of the results from the point of view of these physicists, see De Coppet, *Ann. Chim. Phys.* (4), 23, 366; 25, 502; and 26, 98.

[2] In a Paper read before this Section last year (Report, p. 989), I argued that our formulæ adequately represented the molecules of solids and liquids with which chemical reactions deal, although I fully recognised the existence of far more complex aggregates; my opinions have so far altered that at present I consider these aggregates to be recognisable in many operations which must be termed chemical, although in the great bulk of ordinary reactions the simpler or ultimate molecules need alone be considered.

[1] A power or "affinity" so strong that it will sometimes induce a salt to separate out in a crystalline form and with a proportion of water foreign to its nature, as well as from a solution too weak to yield it of its own accord (Aston and Pickering, "Multiple Sulphates," *Chem. Soc. Trans.*, 1886).

[2] J. M. Thomson, on the "Double Sulphates of Nickel and Cobalt" (*Brit. Assoc. Rep.* 1877, 209).

than the sum of those of its components, and would of itself go far to prove that a solution did in reality contain such a compound. But a rise of temperature would also undoubtedly have another and opposing effect, for, being inimical to the complexity of these hydrates, they would be more dissociated at higher than at lower temperatures, and hence the heat of dissolution would not be so great as it should be according to the various specific heats. This is precisely what Dr. Tilden has proved to be the case (*Proc. Roy. Soc.* 1885, 401).

There is, however, another action which I believe accompanies every act of dissolution resulting in the *absorption* of heat.

The heat absorbed by a large number of salts in dissolving cannot be freely accounted for by the mere physical change of the solid into the liquid salt. Thus, the heat of dissolution of potassium nitrate is −8500 cal., and that of sodium nitrate −5000 cal., whereas the heat of fusion of these salts at the same temperature is but −1300 and −2300 cal. respectively. There must be some other heat-absorbing action besides the fusion of the salt. The amount of heat thus absorbed increases also with the dilution of the liquid. Moreover, we cannot, I think, account for the manner in which heat is evolved in one case and absorbed in another, or the way in which an absorption of heat sometimes gives place to an evolution, as the temperature or other conditions are changed, but by admitting the constant co-existence of two actions producing opposite thermal effects, and being influenced to different extents by an alteration of circumstances.[1]

On the theory which I am here advocating, this absorption of heat receives a ready explanation. Whatever be the complexity of the molecular aggregates of a liquid, those of a solid will be still more complex. Fusion would, therefore, entail their simplification; it would be but a chemical decomposition absorbing heat; this simplification would be pushed much further, however, when the salt is dissolved instead of being merely fused, for the particles of the liquid act chemically (*ex hyp.*) on those of the solid and combine with them themselves; the cold absorbed on dissolution would exceed that absorbed on fusion, and would, moreover, be increased by increasing the amount of the solvent. This accords fully with the facts observed.

All the phenomena attending dissolution are, therefore, I contend, accounted for by a full recognition of the real complexity of the units of matter, and by taking the more liberal view of chemical combination which is inculcated by a study of minerals and other substances. Every act of dissolution involves two actions. The chemical decomposition of the more complex aggregates of the solid into a simpler form, absorbing heat, and a chemical combination of these with the liquid, evolving heat; the only quantity which we can at present measure is the algebraic sum of these two.

Mr. Durham next gave a short statement of his own theory of solution:—

When, for example, common salt (NaCl) is placed in water, all the atoms act upon each other. The sodium of the salt acts upon the oxygen of the water, and the chlorine of the salt upon the hydrogen of the water; and the result is a definite compound, which we call a solution. The heat of formation of the acid is neutralised by the heat of formation of the oxide. If they be not equal, the difference is the heat of the solution; if they be equal, the heat is of course *nil*. If the former be the greater, the heat of the solution is negative; if the latter, it is positive. Solution arises from chemical affinity, and takes place inversely as the attraction between the positive element and the oxygen—and the negative element and the hydrogen—of water. But chemical affinity is itself physical; the atoms are physical, and all forces which act upon them must be physical forces. In a chemical mixture every atom is acting upon every other atom, but such action can be nothing else than physical; and we are therefore led to the conclusion that there is really no difference between chemical and physical action, and, consequently, that the alternative between the two does not exist.

In the course of the discussion, and preceding the reading of Mr. Pickering's paper, the following remarks were made:—

Dr. Armstrong said that, from the summary given by Prof. Tilden, it appeared that the two important questions for discussion were—(1) Does water of crystallisation exist in solution combined with the salt as it did prior to dissolution? and (2) What distinction is to be drawn between chemical combination and mechanical association or adhesion? In short, are the phenomena of dissolution of a chemical or of a mechanical character? But Prof. Tilden had made an important omission, inasmuch as he had not discussed the possible simplification of the molecules on dissolution: in discussing the evidence afforded by the various phenomena, everything turned upon the question whether the crystal molecules are of the composition represented by our ordinary formulæ, or are more or less complex.

As regards the first question, Prof. Tilden appeared to differ from Dr. Nicol, and to think that water of crystallisation did exist in solution. (Prof. Tilden, interposing, desired to explain that what he had said was that it was impossible, in the case of any solution, to say that one portion of the water is in combination with the salt and that another is not; all the phenomena of dissolution and dilution being continuous, no point can be found at which such a distinction can be set up. He believed that the salt was attached to all the water present without exception.)

Dr. Armstrong, resuming, said that much of the evidence appeared, he thought, to favour the conclusion that in certain cases water of crystallisation did exist in solution; *e.g.* the difference in colour between many hydrated and dehydrated salts taken in conjunction with the colour of their solutions. Again, many dehydrated salts dissolved much less readily than the corresponding hydrated salts: instances of this kind were not common among inorganic salts, but were often met with among organic salts, and the speaker cited calcium butyrate and certain naphthalene- and napthol-sulphonates as examples. Dextrose, again, ordinarily crystallises with two molecules of water, but if dehydrated and carefully dissolved in water at a low temperature it may be crystallised out from the solution in the anhydrous state. T. Thomsen's recent experiments, however, appeared to show that when two substances were dissolved in water they appropriated the water in the proportions in which they were present, thus favouring a purely mechanical interpretation of the phenomena of dissolution: but, on the other hand, it was to be noted that in the case of citric and sulphuric acids, for example, Thomsen's results were in accord with this conclusion only when it was assumed that the citric acid was present as the dihydrate, and sulphuric acid as the monohydrate, $H_2SO_4.OH_2$. In fine, the speaker was of opinion that while the question could not be regarded as settled, yet there was a considerable amount of evidence that the water was not evenly distributed, but was, in some cases at least, in part directly combined with the dissolved substance. Dr. Nicol had deduced an ingenious argument from J. Thomsen's observations on heats of neutralisation. As a criticism of Dr. Nicol's argument from the existence of neutralisation constants he would venture to say "Put not your faith in constants." If the views which he held—views which probably were at present peculiar to himself—were correct, the quantities in question ought to have a constant value. According to Helmholtz, all atoms hold a positive or negative electrical charge, a single charge being associated with a monad, two with a dyad, and so on. If when combination takes place these charges exactly neutralised each other, all compounds would be neutral and saturated; but actually this is not the case: in point of fact, there is no such thing as a saturated compound. Helmholtz seems to think that the charges may be held by different atoms with different degrees of force, but the speaker took a somewhat different view, and thought that probably when two atoms combined, in consequence perhaps of peculiarities of structure, their charges were not completely used up; the resulting molecules therefore possessed a certain residual charge or affinity, and were consequently in a position to enter into combination with other molecules. Thus water, he thought, was not a saturated compound; its oxygen atom was still possessed of residual affinity. The same was true of sulphuric acid. Consequently the two could combine together to form a hydrate. On neutralising a dilute solution of alkali by a dilute solution of acid, a stable condition is finally attained, and it is to be assumed that the affinities are fully satisfied, or very nearly so—that the charges practically neutralise each other: hence it may be expected that the heat of neutralisation will have nearly a constant value provided there be no disturbance such as the separation of a precipitate would produce. But the value of each of the several processes which go to make up the heat of neutralisation are entirely unknown to us, and in the absence of such knowledge it

[1] A study of the thermal results attending the dilution of salt-solutions, established by Thomsen ("Thermo-chem.," iii., especially plate iv., and also the curves given by formic and acetic acids and by potassium and sodium hydrates), impresses very forcibly the co-existence of these two actions, although Thomsen himself does not seem to have noticed it.

is impossible to place much confidence in arguments based upon the study of such complex phenomena.

As regards the question of chemical *versus* mechanical action, the speaker could only imagine one form of mechanical action attending dissolution, viz. that of the water molecules bombarding the surfaces of the solid, and as it were chipping off particles. All other actions, in so far as they could be regarded as involving the attraction of the molecules of the dissolved substance by those of the solvent, he was inclined to class as chemical. Nothing was more certain than that dissolution depended on the nature both of the solvent and of the substance dissolved. Like dissolves like—water is *the* solvent for bodies containing oxygen; sulphur compounds are dissolved by carbon bisulphide; phosphorus compounds by chloride of phosphorus; shale spirit, which is rich in olefines, and especially rosin spirit, which is rich in acetylenes and benzenes, were far better solvents of hydrocarbons and resinous bodies than petroleum, which consisted of saturated inert hydrocarbons, and was the worst of solvents. Facts such as these spoke strongly in favour of the conclusion that the phenomena of dissolution are largely of a chemical character.

Prof. W. N. Hartley was understood to base the argument in favour of the hydration theory chiefly on the changes of colour observed in the solution of certain salts in various proportions of water. The chlorides, bromides, and iodides of cobalt, nickel, and copper exhibit these phenomena most plainly. Thus the iodide of cobalt in the anhydrous state is black, its dihydrate is green, the hexhydrate a reddish brown. If this last be dissolved in water a pink solution is formed, which probably contains a richer hydrate. The brown saturated solution of the hexhydrate is a very dense liquid, of specific gravity about 3, and when water is added to it the formation of the pink liquid is attended by a large evolution of heat, and this affords evidence that the hydrate exists in the solution. Again, hydrated cupric chloride contains two molecules of water, and when quite dry is of a pale blue colour. Its solution in water has the same colour unless it be heated, and then it turns green. Nickel salts behave similarly. So that the evidence, on the whole, warrants the belief that when a hydrated salt is dissolved in water the water of crystallisation remains a constituent part of the molecule.

Dr. Gladstone commenced his remarks by a discussion of the question, What is a salt in solution? Is the solution of a salt in water a process analogous in any degree to the decomposition which takes place when one salt is mixed with another? Take, for instance, chloride of sodium and water. Many years ago the speaker had endeavoured to determine whether any chemical decomposition of the salt by the water occurred so as to give rise to sodium hydrate and hydrochloric acid, but he had come to the conclusion that this decomposition took place, if at all, only to a very small extent. Many salts, as had already been stated, combine with water to form coloured hydrates, and the hydrate is of a colour different from that of anhydrous salt. But a coloured hydrate, when dissolved in a sufficient quantity of water, is never changed by further dilution. The speaker had endeavoured to ascertain whether the specific refraction of substances was altered by solution. He had found that no alteration could be detected, and this result was afterwards confirmed by the experiments of other chemists. The refraction equivalent of a solution is equal to the sum of the refraction equivalents of the salt and the water present. In an alum solution, the water of crystallisation supposed to be in combination with the salt is not distinguishable by its refractive power from the water of solution outside it. It seems impossible, however, to arrive at a conclusion with regard to the constituents of a solution. The idea of reciprocal decomposition is not supported by experimental evidence, save in some exceptional cases, and the actual condition of a dissolved salt seems beyond expression by formulæ.

TEN YEARS' PROGRESS IN ASTRONOMY[1]

THE Earth.—In what may be called the astronomy of the earth there is no very great discovery, nothing extremely new and brilliant to record during the past decade; but there has been considerable and steady progress.

(*a*) As regards the earth's form and dimensions, it has become quite certain that Bessel's ellipticity (1/300) is too small. Clarke's value of 1/294 is now admitted and employed on the U.S. Coast Survey with a decided improvement of accordance. A slightly larger value even is suggested by the most recent pendulum observations, and 1/292 is now adopted in Europe.

One of the most important steps in this branch of investigation is the discovery by Mr. Peirce (of our own Coast Survey), of the large correction required in many former pendulum determinations, on account of the yielding of the stand from which the pendulum is suspended.

During the past ten or fifteen years a great amount of material has been collected towards a complete gravitational survey of the earth, by the work of Lieut.-Col. Herschel in India, and of the officers of the Coast Survey in this country and elsewhere, and a very important part of it has consisted in connecting the older work with the new, by Peirce's operations in Europe, and those of Herschel in this country.

At the same time it has become increasingly evident that very little is now to be gained by endeavouring to find a spheroid fitting the earth's actual form more closely. It will be best simply to adopt some standard (say that of Clarke, but it makes very little difference what), and to investigate hereafter the local deviations from it. These deviations seem to be larger and more extensive than used to be supposed, the station errors in latitude and longitude being at least quantities of the same order as the variations of elevation.

We mention, in passing, the investigations of Fergola, based on observations at Pulkowa and Greenwich, and leading to a suspicion that the axis of the earth is slightly changing its position and shifting the place of the Poles on the earth's surface. Operations have been organised to determine the question by co-operation between different observatories in nearly the same latitude, but widely differing in longitude.

Nor ought we to pass unnoticed an elaborate paper by Kapteyn, of Groningen, on the determination of latitude by a method depending upon time-observation of stars, at equal altitudes, though in widely different parts of the sky; the stars being so selected that all errors of star-places, instrument, and clock, are almost perfectly eliminated. In the same connection we ought to mention also the new equal-altitude instrument, the Almucantar, invented by Chandler, of Cambridge, and his development of the method of determining time by its use. It may possibly supersede the transit instrument for this purpose, as he seems to expect, though we think it hardly likely.

Rapid progress has been made in determining the difference of longitude between all the principal parts of the earth. There now remain very few stations of much importance which have not their longitude from Greenwich telegraphically settled within a small fraction of a second. In Europe Albrecht has combined into a consistent whole all the different data for more than one hundred points. Our American system has been similarly worked out by Schott, and is connected with the European by no less than four different and independent cable-determinations. South America is connected with the United States by the recent operations of our naval officers in the West Indies and along the eastern and western coasts of the continent; and with Europe by a cable connection between Lisbon and Pernambuco, also effected by them. It is worth noting that two large errors in European longitudes owe their detection to American astronomers. The difference of longitude between Greenwich and Paris was corrected by our Coast Survey in 1872 to the extent of nearly half a second of time, and our naval officers in 1878 showed that the then received longitude of Lisbon was 8·54s. too small! It is a less surprising fact that an error of 35s. was found in the longitude of Rio.

Our navy has also determined an important series of telegraphic longitudes along the eastern coast of Asia and through the East Indies. The French have been doing similar work in the same regions, especially in connection with the transits of Venus; and the English have determined a large number of longitudes in India. These Asiatic longitudes have been recently connected with Australia and New Zealand by English astronomers, and a telegraphic longitude connection has been effected down the eastern coast of Africa from Aden to the Cape; so that now it is perfectly practicable, if it is desirable, to have one standard of time in all the civilised world.

A word perhaps is here in place as to this question of standard time and the beginning of the day. The adoption by our railroads of the system of standards differing from Greenwich time only by entire hours has, I think, been admittedly a great step in advance, as regards public convenience and safety in travelling. At a few points, where standard and local time happen

[1] "Ten Years' Progress in Astronomy, 1876-86," by Prof. C. A. Young. Read May 17, 1886, before the New York Academy of Sciences.

to differ by nearly the maximum possible amount of half an hour, some annoyance is felt, and there is still some opposition; but it seems quite clear that, in this country at least, all resistance will soon die out.

As regards the more purely astronomical question of making the astronomical day coincide with the civil day, by beginning at midnight, instead of noon, as it does at present, there is more difference of opinion. For my own part, I am frankly in favour of the change, because I see no use in perpetuating an anomaly which is sometimes annoying and confusing. At the same time the change would, of course, involve some inconvenience to computers and night-observers, and it must be admitted that at present a large number, and possibly a majority, of the most eminent astronomers, in other countries as well as in this, are opposed to it. Those of us whose work falls about as much in the day as in the night, and those, I think, who take a long look ahead, are in favour of the reform; but those whose work is mainly nocturnal, or is based on observations made chiefly at or near the "witching hour," dread the inconvenience of a change of date in the midst of the record, and the risk of confusion in the interpretation of old observations.

The question, however, seems to me not a very important one.

I notice that the visitors of the Royal Observatory have just recommended that the change be introduced into the British *Nautical Almanac* for 1891.

Before passing to the moon, a word should be added as to the outcome of the most recent investigations regarding the steadiness of the earth's rotation. Some irregularities in the lunar motions have appeared to justify a suspicion, at least, that they might be caused by irregularities in the length of the day. The researches of Newcomb upon ancient eclipses and occultations of stars give results not necessarily inconsistent with this hypothesis, perhaps even slightly in its favour, but his careful examination of the past transits of Mercury contra-indicates it pretty decidedly.

The Moon.—During the past ten years there has been no work upon the lunar theory quite on a level with that of Hansen, Delaunay, Plantamour, and Adams in the years preceding; but the labours of Neison, Hill, and Newcomb well deserve mention. The former especially has carried his approximations to a considerably higher point than any of his predecessors, though not without making a few numerical mistakes, which have been detected and corrected by Hill. The investigation of ancient and mediæval observations of the moon by Newcomb is also a very important work, as showing clearly that the lunar theory is still incomplete, and that it is impossible by any tables yet made to represent accurately the whole series of observations. A value of the secular acceleration which suits the observations of the last 200 years will not fit the Arabian observations made 1000 years ago, nor will it satisfy the eclipse observations of still more ancient date, unless at least the received interpretation of those ancient eclipses be admitted to be wrong, as Prof. Newcomb seems to consider rather probable. From his discussion he derives for the secular acceleration a value of 8″·4, as against the value of 12″·1, deduced by Hansen.

It will be remembered probably by every one present that the *theoretical* value of this quantity is about 6″, and that Ferrel, Adams, Delaunay, and others, attributed its apparent increase to 12″ to the action of the tides in retarding the earth's rotation and so lengthening the day; if Newcomb's value is correct, this tidal retardation is cut down from 6″ to about 2″·5.

The study of the moon's surface has been carried on with assiduity, but I do not know that any remarkable results have been reached, though Klein's observation, in 1877, of what he supposed to be a newly-formed crater (Hyginus N.), excited a good deal of interest and discussion for a number of years; and the most eminent selenographers are still divided in opinion on the question.

The publication by the German Government of Schmidt's great map of the moon, in 1878, unquestionably marks an epoch in selenography; and the photographic work of Pritchard, and the heliometric determination of the moon's physical libration by Hartwig, must not pass unnoticed.

Probably, however, the lunar work which has drawn to itself most attention and interest is the investigation of the moon's heat by Lord Rosse and Prof. Langley.

The earliest observations of the kind date back now forty years, when Melloni, in 1846, first detected the moon's heat by means of the then newly-invented thermopile. But the first really scientific *measurements* are only about fifteen years old, due to Lord Rosse, at Parsonstown, and to Marie Davy, at Paris; and they seemed to show that at the time of full moon we receive from our satellite, not merely *reflected* heat, but warmth *radiated* from the moon's surface; as if this surface were raised to a considerable temperature by the long insolation to which it has been exposed during the preceding fortnight. Lord Rosse estimated the probable temperature of this heated rock to be as high as from 300° to 500° F.

But within the past four or five years this conclusion has been called in question. Observations at Parsonstown, of the rapid diminution of radiation during a lunar eclipse, seem to favour the newer view that the moon's surface, like that of a lofty mountain-top on the earth, never gets very hot, since the absence of air enables the solar heat to escape nearly as fast as it is received.

Prof. Langley's recent and still progressing work upon this subject far excels in delicacy and elaborateness anything done before. At first it seemed to show that the temperature of freezing water was never reached even at the hottest parts of the lunar surface; but the later observations throw some doubt on the legitimacy of this inference. It is found that the radiation from the moon unquestionably contains a considerable percentage of rays which have a wave-length *longer* than any of the heat-rays from melting ice; and this fact has been supposed to make it probable that the moon's surface was colder than the ice. But then, within a few weeks, Prof. Langley has found the long-waved rays in the radiation from an *electric arc!* So the question still hangs debatable.

The Sun's Parallax.—I think we may say that, during the past ten years, substantial progress has been made with the problem of the solar parallax. The transit of Venus in 1882 adds whatever value its results may have to those obtained eight years before; but, on the whole, so far as can be judged from the reductions thus far completed and published, it would seem likely that the outcome of the transit observations will be simply to confirm the results obtained by other methods. It may be that the data obtained from the German heliometer measurements will prove more accordant and decisive than those derived from photographs and from the contact observations; there are flying rumours that they will, but it will be necessary to await the official publication for certain knowledge on this point. If they do not, we shall be obliged, hereafter, to relegate transit observations to a secondary rank, as a means of determining the sun's distance. From the various observations of the two transits, different computers have deduced values of the parallax all the way from 8″·6 to 8″·95, corresponding to a distance ranging from 95,000,000 to 91,500,000 miles.

The case is quite different with the heliometer observations of the opposition of Mars, in 1877, made by Mr. Gill at Ascension Island. These give, in a most definite and apparently authoritative manner, a value of 8″·783, and are apparently irreconcilable with any value much greater than 8″·81, or less than 8″·75. So far as can be judged from the number, nature, and accordance of the observations, I believe we must accept this as the most trustworthy of the geometrical methods yet employed; though the weight of the result would certainly be increased if it did not depend to such an extent upon the work of a single individual.

The confidence of astronomers in the correctness of this value is greatly fortified by the fact that the most recent and reliable determinations of the velocity of light, made by Michelson and Newcomb, in 1877, 1880, 1881, and 1882, when combined with the Pulkowa constant of aberration determined by Nyrèn from all the data available up to 1882, give a solar parallax accordant with the preceding almost to the hundredth of a second—8″·794 as against 8″·783. It is true there are possible theoretical objections to the method; as, for instance, that the result may be slighted affected by the motion of the solar system through space. Enough is not known certainly about the constitution of the medium that transmits light through space, to decide all such questions *a priori* and authoritatively; but it is unquestionable that any correction needed on account of such possible causes of error must be very minute.

We believe, therefore, that it is safe to assume pretty confidently that the solar parallax is about 8″·8 (though probably a trifle less), which makes the sun's mean distance 93,000,000 miles, with an error not likely much to exceed 150,000 miles. A larger value of the parallax (about 8″·85) still holds its ground in the nautical almanacs, and undeniably is nearer the *average* of the results given by *all* the known methods. But none of the other methods seem to us to compete at all in precision with the two whose authority we accept.

The Sun and Meteorology.—The study of the solar surface has been carried on very persistently by Spörer, in Germany, as well as by others, and a great amount of material has been collected bearing upon the theory and nature of sunspots, and their periodicity. The extensive series of photographs obtained at Kew, and at Dehra Doon, in India, constitutes almost a continuous record of the solar surface for several years. The relation between this periodicity and terrestrial conditions has been assiduously examined, but on the whole the outcome seems to me to leave this connection as doubtful as it ever was, in most cases at least. While in some parts of the earth it looks as if there were a slight but marked increase of storm and rainfall at the time of sunspot maximum, the reverse seems to be true in other countries. In South America, Dr. Gould thinks that he has demonstrated a very perceptible effect of the condition of the sun's surface in modifying the strength and direction of the winds; but thus far similar investigations elsewhere show no such result. It will evidently be necessary to wait for a longer and more widely extended collection of statistics to settle the question. We do not even know as yet whether we get more or less than the average heat from the sun during the sunspot maximum.

But I think it may be set down as certain that the condition of the sun's surface exerts, if perhaps a real, yet only a very slight effect upon our earthly meteorology. With terrestrial magnetism the case is markedly and singularly different, and one of the most interesting problems now pressing for solution is the nature of the connection between solar disturbances and magnetic storms.

Solar Heat.—A great deal of labour has been expended upon the study of the sun's heat during the last decade. The investigations that strike me on the whole as most worthy of mention are those of our own Langley and of the Italian Rosetti, whose early death a few months ago is a great loss to science. Secchi and Ericsson, on the one side, had contended for a solar temperature of some millions of degrees, basing their results on Newton's law of cooling; while, on the other, Crova and Violle, from their measures of the solar radiation, reduced according to the so-called law of Dulong and Petit, maintained that the temperature does not much exceed that of many terrestrial furnaces, somewhere from 1500° to 2500° C. Rosetti's experiments upon the radiation of the electric arc and other sources of intense heat showed pretty clearly the inapplicability of Dulong and Petit's law to high temperatures, and indicate a solar temperature not far from 10,000° C., or 18,000° F. But they also make it clear that the limits of uncertainty are still very great.

Prof. Langley, by his invention of the bolometer, has been able to investigate separately the amount of energy transmitted to the earth in the solar rays of every possible wave-length, and to determine the effect of our atmosphere in absorbing each kind of ray. He has shown that the older method of investigating this solar radiation, *in a lump* so to speak, gives fallacious results on account of atmospheric absorption; and that the necessary correction compels us to increase our estimate of the sun's energy at least 20 per cent. In my own little book upon the sun, published in 1881, I had set the so-called solar constant at twenty-five calories per square metre per minute. It is now certain that it must be put at least as high as thirty. Prof. Langley's investigations seem also to show another remarkable fact—that we do not receive from the sun any at all of the low-pitched, slowly-pulsing waves, such as we get from surfaces at or below the temperature of boiling water. The solar spectrum appears to be cut off abruptly at the lower end; and this cutting off we know cannot have been effected in the earth's atmosphere, because we receive from the moon in considerable quantity just this very sort of low-pitched rays. Langley finds them also abundant in the radiation of the electric arc, so that we can hardly suppose them to be *originally* wanting in the solar heat. It now looks as if we must admit that they have been suppressed either in the atmosphere of the sun itself, or in interplanetary space. Another striking conclusion first clearly pointed out by Langley is that, if the sun's atmosphere were removed, its light would be strongly blue.

The Solar Surface and Spots.—As regards the general make-up of the solar surface, I do not think there has been any new fact of extreme importance brought out within ten years. Janssen has, however, carried solar photography to higher excellence than ever attained before, and has obtained plates that show the "granules" and their grouping on a scale previously unknown. He thinks that his plates prove a peculiar constitution of the solar surface, consisting in collections of clearly-defined and rounded granules, separated by regions or streaks where they are ill defined and elongated; and he calls the phenomenon the "reseau photosphérique," or photospheric network. According to him the "net" remains approximately constant for some minutes at a time, as shown by plates taken in quick succession, but is subject to rapid and enormous changes in periods exceeding a quarter of an hour or so. I find some scepticism among high authorities as to the trustworthiness of his conclusions. There are suggestions that the appearances presented may be due to currents of air in the telescope tube and at the surface of the sensitive plate; but I am disposed to think he is right, for, on several occasions when the seeing has been exceptionally fine, I have observed with my own eyes something quite analogous, in our large telescope at Princeton.

The spots have been carefully studied by several observers, by Spörer especially, in a statistical way, and by Vogel, Lohse, Tacchini, and others, as to structure and detail. Spörer has brought out very clearly the connection between the number and average latitude of the spots. It appears that, speaking broadly, the disturbance which produces the sunspots begins in two belts on each side of the sun's equator in a latitude of over 30°; these belts or spot-zones then gradually move in towards the equator, the sunspot maximum occurring when their latitude is about 16°, while the disturbance gradually and finally disappears at a latitude of 8° or 10°, some twelve or fourteen years after its first appearance. But two or three years before this disappearance a new zone of disturbance shows itself in the same latitude as its predecessor, so that for a while, about the time of sunspot minimum, there are two well-marked zones of spots on each side of the sun's equator—one pair near the equator, due to the expiring disturbance which began some ten or eleven years ago; the other far from the equator, and due to the newly-arising outburst, which will reach its maximum in three or four years, and then pass away like the former.

There can be no doubt that the phenomenon is a very significant one, but its explanation, like that of the periodicity itself, is still to be found.

Nor is the problem of the spots themselves yet fully solved. Not that there is any reasonable question that they are *hollows* in the solar photosphere; but how they originate, how deep they are, and what are the causes of their darkness, and the condition and temperature of the darkening substance—these are questions to which only uncertain answers can now be given. A long and important series of observations upon the widening of the lines of certain elements in the sunspot spectra has been made by Mr. Lockyer, and establishes clearly the fact that those lines, of *iron* for instance, which are conspicuously black and wide in the sunspots, are often just those which do *not* show themselves conspicuously in the prominences; and moreover both in spots and prominences the iron lines that do show themselves are most frequently those which closely coincide with lines in the spectra of other substances. Singularly, also, and so far quite without explanation, it appears according to his observations that at the sunspot maximum those *iron* lines which at other times are conspicuous in spot-spectra entirely disappear.

Perhaps I may be allowed to mention here a recent observation of my own upon these spot-spectra: with a high dispersion the darkest part of the spot-spectrum is found to be not continuous, but made up of fine lines overlapping or almost touching each other, with here and there a clear space left, like a fine bright line. It means, I think, that the absorbing vapours which darken the interior of the spot are wholly gaseous, and tends to disprove the idea that they are mostly of the nature of smoke or steam. We mention also, in passing, another thing which has been shown by our large instrument at Princeton—that the apparently bulbous, finger-tip-like terminations of the penumbral filaments are often, under the best circumstances of vision, resolved into fine, bright, sharp-pointed hooks which look like the tips of curling flames.

(To be continued.)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—At the biennial election of members of the Council of the Senate, Prof. Michael Foster and Dr. Donald MacAlister were elected to serve for four years.

SOCIETIES AND ACADEMIES

London

Mathematical Society, November 11.—Mr. J. W. L. Glaisher, F.R.S., President, in the chair.—Mr. F. S. McAulay, St. Paul's School, was elected a Member.—The following gentlemen were elected to form the Council for the ensuing session:—President: Sir J. Cockle, F.R.S.; Vice-Presidents: J. W. L. Glaisher, F.R.S., Prof. Harry Hart, and the Right Hon. Lord Rayleigh, Sec. R.S.; Treasurer: A. B. Kempe, F.R.S.; Hon. Secretaries: Messrs. M. Jenkins and R. Tucker; other Members: Prof. Cayley, F.R.S.; E. B. Elliott, Prof. Greenhill, J. Hammond, Prof. M. J. M. Hill, C. Leudersdorf, Capt. Macmahon, R.A., S. Roberts, F.R.S., and J. J. Walker, F.R.S.—The retiring President, J. W. L. Glaisher, F.R.S., delivered an address, which treated of the Mathematical Tripos Examinations at Cambridge, and of the bearings of recent changes in the same upon the advancement of mathematics.—The following communications were made:—Certain operators in connection with symmetric functions, by R. Lachlan.—The transformation of a certain quartic elliptic element, by R. Russell.—Discussion of a multilinear operator, with applications to the theories of invariants and reciprocants, by Capt. Macmahon.—The theory of screws in elliptic space (fourth note), by A. Buchheim.—The rectification of certain curves, by R. A. Roberts.—Rectification of a sphero-conic, by H. F. Burstall.—Third paper on reciprocants, by L. J. Rogers.—The "sine-triple-angle" circle, by R. Tucker.

Linnean Society, November 4.—Mr. William Carruthers, F.R.S., President, in the chair.—The President paid a passing tribute to, and commented on the loss sustained in the death of, Mr. George Busk, a former Secretary and Vice-President of the Society. Afterwards he drew attention to phosphorescent organisms obtained by him in the Firth of Clyde last September.—Mr. John Murray also made remarks on the same, alluding to his own observations of *Ceratium tripos* being found in long chains in the ocean ("Narrative of the Cruise of the *Challenger*"), and to Klebs's opinion of *Ceratium* being a genus of unicellular Algæ, and not an infusorian.—Prof. J. Macoun made remarks on a series of cones of Canadian *Piceas*. He showed that the various forms occurring from east to west of the continent, which had been hitherto considered different species, were doubtless local varieties of but one species, slightly modified according to the altitudes and region they inhabited.—Dr. F. Day exhibited a salmon parr, twenty months old, raised at Howietoun from parents which had never visited the sea. He also showed coloured drawings of hybrids raised in the same establishment—one being a cross between the American charr and the Loch Leven trout, a second between the American and the British charr, and a third between the last-mentioned hybrid and the Loch Leven trout; all were fertile.—Fresh specimens of a white variety of *Crocus nudiflorus* from Biarritz, France, were shown for Mr. W. D'Arcy Godolphin Osborne, who first observed the variety there in 1882, but since then it has been figured by Mr. G. Maw in his monograph of the genus.—Mr. E. M. Holmes exhibited examples of *Lycoperdon echinatum*, Pers., viz. the young plants, and the reticulate appearance of the peridium left by the falling off of the spines.—Mr. F. Pascoe exhibited one of the round olive green balls from Sicily, formed by the action of the sea on fragments of the *Posodonia caulinia*, and reduced, after a few days' exposure, to a flat cake-like body densely covered with minute crystals of salt. He also showed some acorn-shells (*Balanus*), where several individual animals had united their shells into a common tube, and where the outer valves of each animal had lengthened, forming a series of irregular subsidiary tubes radiating from the apex of the primary one.—Mr. E. C. Bousfield read a paper on the natural history of the genus *Dero*. In this he gives a full account of their habits and the best method of observing them. The *Naias digitata*, Müll., he rejects as a specific appellation, Müller's reference being defective. He shows wherein the Deros differ from the Naiades, viz. in the former having a respiratory apparatus at the end of the tail. He diagnoses seven species, four being new; all are figured.—Mr. S. O. Ridley gave in abstract his researches on the genus *Lophopus*, and description of a new species from Australia. This latter, *L. lendenfeldi*, obtained by Dr. Lendenfeld near Sydney, N.S.W., is distinguished from *L. crystallinus* by length of tentacles equalling the body of the polypide, and by the non-pointed outline of the statoblast. The new species is the fourth fresh-water Polyzoon recorded from Australia, and the first of its genus satisfactorily determined from the southern hemisphere. Staining with borax-carmine brings out multipolar cells in the ectocyst, indicating mesodermal elements, and denoting that the ectocyst is something more than mere epithelium. A modification of the diagnosis of the genus is necessitated from these observations.

Chemical Society, November 4.—W. Crookes, F.R.S., Vice-President, in the chair.—Messrs. H. Crompton, G. Dyson, T. B. Tyson, and S. Williamson were admitted Fellows of the Society.—The following papers were read:—The action of chlorosulphonic acid on naphthalene-α- and β-sulphonic acids, by Henry E. Armstrong and W. P. Wynne, B.Sc.—The action of bromine on (Schäfer's) β-naphtholsulphonic acid, by Henry E. Armstrong and F. W. Streatfeild.—The action of bromine on the naphthalenesulphonic acids, by Henry E. Armstrong and W. P. Wynne, B.Sc.—α-Nitro-, α-bromo-, and α-chloronaphthalenesulphonic acids, by Henry E. Armstrong and S. Williamson.—The hydrolysis of sulphonic acids, by A. K. Miller, Ph.D.—The action of bromine on tolueneparasulphonic acid, by A. K. Miller, Ph.D.—Phosphorus tetroxide, by T. E. Thorpe, F.R.S., and A. E. Tutton.—Conversion of ditolane-azotide into diphenanthrylene-azotide, by Francis R. Japp, F.R.S., and Cosmo Innes Burton, B.Sc.—A chemical study of vegetable albinism; part 3, experiments with *Quercus rubra*, by A. H. Church.—The synthetical formation of closed carbon-chains; part 2, some derivatives of tetramethylene, by W. H. Perkin, Jun., Ph.D.—The action of the halogens on the salts of organic bases; part 2, tetramethylammonium salts, by Leonard Dobbin, Ph.D., and Orme Masson, M.A., D.Sc.—Glycyphyllin, the sweet principle of *Smilax glycyphylla*, by Edward H. Rennie, M.A., D.Sc.

Entomological Society, November 3.—Mr. Robert McLachlan, F.R.S., President, in the chair.—The following gentlemen were elected Fellows:—Messrs. P. Cameron, F. Archer, H. J. S. Pryer, H. Norris, N. P. Fenwick, J. Brown, J. P. Tutt, and A. P. Green.—Mr. E. B. Poulton exhibited a mass of minute crystals of formate of lead, caused by the action of the secretion of the larva of *Dicranura vinula* upon suboxide of lead. He stated that a single drop of the secretion had produced the crystals which were exhibited; and he called attention to the excessively high percentage of formic acid which must be present in the secretion.—Mr. S. Stevens exhibited a specimen of *Laphygma exigua*, recently captured by Mr. Rogers in the Isle of Wight.—Mr. W. F. Kirby exhibited, and read notes on, a specimen of *Perilampus maurus* recently bred by Mr. Walter de Rothschild from *Antheræa tirrhea*, one of the rarer South African Saturnidæ.—Mr. T. W. Hall exhibited a number of specimens of *Xanthia fulvago* (*cerago*), somewhat remarkable in their variation, and showing a graduated series, extending from the pale variety, *flavescens* of Esper, to an almost melanic form.—Mr. Boyd exhibited, and made remarks on, the larva of a species of *Ornithoptera* from New Guinea.—Mr. H. Goss exhibited a series of *Bankia argentula* collected by him in Cambridgeshire in June last; and also, for comparison, a series of specimens of the same species taken at Killarney in June 1877. It appeared that the Irish form of the species was larger and more brightly coloured than the English form.—Mr. Eland Shaw exhibited a female specimen of *Decticus verrucivorus* taken in July last at St. Margaret's Bay, Kent.—Mr. Waterhouse recorded the recent capture of *Deiopeia pulchella* at Ramsgate, by Mr. Buckmaster; and the capture of *Anosia plexippus* at Gibraltar was also announced.—Mr. J. W. Slater read a paper on the relations of insects to flowers, in which he stated that many flowers which gave off agreeable odours appeared not so attractive to insects as some other less fragrant species; and he stated that Petunias, according to his observations, were comparatively neglected by bees, butterflies, and Diptera. Mr. Distant, Mr. Stainton, Mr. Weir, Mr. Stevens, and the President took part in the discussion which ensued, and stated that, in their experience, Petunias were often most attractive to insects. Mr. Stainton referred to the capture, by himself, of sixteen specimens of *Sphinx convolvuli* at the flowers of Petunias, in one evening in 1846.—Jonkeer May, the Dutch Consul-General, asked whether the reported occurrence of the Hessian fly (*Cecidomyia destructor*) in England had been confirmed. In reply, Mr. McLachlan stated he believed that several examples of an insect, thought to be the Hessian fly, had been bred in this country, but that everything depended upon correct specific determination in such an obscure and difficult genus as *Cecidomyia*.

EDINBURGH

Mathematical Society, November 12.—Dr. R. M. Ferguson, President, in the chair.—The President gave a retiring address, for which, and for the gratuitous use of the rooms of the Edinburgh Institution for the Society's meetings a vote of thanks was awarded to him.—Mr. J. S. Mackay read a paper on the solutions of Euclid's problems with a ruler and one fixed aperture of the compasses by the Italian geometers of the sixteenth century; and communicated a note from Mr. R. Tucker giving some novel properties connected with the triangle.—Mr. A. Y. Fraser read a note by Mr. William Renton on the equivocal sign.—The following office-bearers were elected for the session:—President: Mr. George Thom; Vice-President: Mr. W. J. Macdonald; Secretary: Mr. A. Y. Fraser; Treasurer: Mr. John Alison; Committee: Mr. R. E. Allardice, Dr. R. M. Ferguson, Mr. George A. Gibson, Mr. William Harvey, Mr. J. S. Mackay, Mr. Thomas Muir.

SYDNEY

Royal Society of New South Wales, September 1.—Mr. Ch. Rolleston, President, in the chair.—Mr. Fredk. B. Gipps, C.E., read a paper on "Our Lakes and their Uses." The lakes of New South Wales being all liable to dry up, Mr. Gipps stated that it is possible, however, to impound large artificial lakes. The leading features of Lake George were described, and a means of utilising its waters for irrigating a large area were entered into.—A very beautiful specimen of gold from calcite was exhibited by Dr. Leibius, of the Mint. The lime having been dissolved in acid, the gold was left as a network of the finest ramifying filaments.

PARIS

Academy of Sciences, November 8.—M. Jurien de la Gravière, President, in the chair.—On the relations of geodesy and geology, by M. Faye. This is a reply to M. de Lapparent's recent criticisms of the author's well-known views on the relations of the geodetic and geological sciences. M. de Lapparent's objections are treated in detail, and it is argued that the law of unequal cooling of the terrestrial crust dates back to times anterior to the astronomico-geological epoch, when the seasons began to be established. It controlled the whole series of geological evolutions from the first formation of the oceanic basins.—Thermic researches on the reactions between ammonia and the magnesian salts, by M. Berthelot. These studies tend to define the action of ammonia on the magnesian salts, determining the analytical conditions which enable magnesia to be separated from the other alkaline salts, and showing that, by union with sulphuric acid or with hydrochloric acid, the complex ammoniaco-magnesian base liberates a quantity of heat greater than pure ammonia or pure magnesia, and very near that liberated by potassa and soda.—On the incandescent substance in fusion recently reported to have fallen during a thunderstorm at Luchon, by M. A. Trécul. In connection with M. St. Meunier's remarks on this subject, the author refers to a communication made by him to the Academy in 1881 (*Comptes rendus*, xcii. p. 775), showing that in thunder-clouds there may exist an incandescent substance in fusion, which under certain conditions may fall to the ground in the form of variable drops or globules.—Report made on behalf of the Section for Chemistry on M. Moissan's researches relating to the isolation of fluor, by M. Debray. After describing the attempts made by Davy and subsequent chemists to solve this problem, the report gives a detailed account of M. Moissan's researches, and considers his final conclusion fully justified, that the gas liberated by the electrolysis from the pure anhydrous hydrofluoric acid, with which he experimented, is undoubtedly fluorine. The question consequently now enters on a new phase, and chemistry may henceforth deal directly with fluorine, and attack problems of great interest, formerly regarded as insoluble.—Observations of the new planet 261, made at the Paris Observatory (equatorial of the West Tower), by M. G. Bigourdan.—On an extended class of uniform transcendants, by M. H. Poincaré.—On Maclaurin's series in the case of a real variable: application to the development of a homogeneous body in series of the potential, by M. O. Callandreau.—Note on the octahedron, by M. P. Serret.—On the transport of force; a reply to M. Deprez, by M. Hippolyte Fontaine. It is admitted that the principle of a series of machines linked together is not new; but the author claims that the results of his researches obtained by the employment of special dynamos, and by a rearrangement of the mechanical elements, must be regarded as new. The transport of 50 horse-power through a resistance of 100 ohms with a loss of only 48 per cent., by employing dynamos jointly weighing only 8400 kilograms and costing only 658*l.*, is now realised for the first time.—Determination of the heats of neutralisation of the malonic, tartronic, and malic acids: remarks on the heats of neutralisation of the homologous acids of oxalic acid and of the corresponding hydroxyletted acids, by MM. H. Gal and E. Werner. The results here tabulated of the authors' researches show that the heat of neutralisation of the homologous bibasic acids under consideration diminishes in proportion as the molecular weight increases.—General methods of crystallisation by diffusion; reproduction of mineral species, by M. Ch. Er. Guignet. These experiments are described as a generalisation of M. Becquerel's ingenious researches on the slow action set up between two liquids separated by a film, a porous wall, or even a glass tube with a fissure or capillary aperture. The methods employed are applicable to a large number of bodies, and yield crystals in any required quantities.—Synthesis of conicine, by M. A. Ladenburg. The processes are described by which the author has succeeded in obtaining synthetically three bases possessing the same mutual relations as racemic and tartaric acids, one of which is absolutely identical with natural conicine.—On the chemical transformations brought about by the action of solar light, by M. E. Duclaux. Having already examined the sterilising action of solar light on microbes, the author here proceeds to show that the influence at play belongs to the order of chemical phenomena, which in this case assume a physiological character. The action of the solar rays is shown to be analogous to that of the ferments.—On a new means of preventing secondary fermentations in the alcoholic fermentations of commerce, by MM. U. Gayon and G. Dupetit. This process consists in adding to the wort antiseptic substances capable of arresting the development of the countless germs contained in the primary substances and in the yeast, without, however, impairing the activity of the leaven itself.—On the alcoholic fermentation of dextrine and of starch, by MM. U. Gayon and E. Dubourg. A new kind of mucor is described, which possesses the twofold property of fixing the water on dextrine, and even on starch, and superinducing fermentation in the products of this saccharification, without, however, affecting cane-sugar or transforming it to alcohol.—On the reduction of the sulphate of copper during vinous fermentation, by M. H. Quantin.—On the genus Cepon, by MM. A. Giard and J. Bonnier. Two new species (*C. pilula* and *C. elegans*) of this little-known genus have been discovered by the authors, the former a parasite of *Xantho floridus*, the latter of *Pilumnus hirtellus*. Both occur on the French seaboard.—On the homologies of the larvæ of Comatulæ, by M. J. Barrois.—On the cave-dwellers of Bêche-aux-Roches, by MM. Marcel de Puydt and Max. Lohest. The authors disclaim all responsibility for the recent remarks of M. de Nadaillac describing the culture of this prehistoric race in somewhat exaggerated language.—On the affinities of the Eocene floras of West France and Saxony, by M. Louis Crié.—On a serious malady analogous to scurvy observed in certain reptiles, by M. Magitot.—On a technical process for the diagnosis of Gonococcus, whereby this parasite may be distinguished from other species of cocci, by M. Gabriel Roux.

BERLIN

Meteorological Society, November 2.—Prof. von Bezold in the chair.—Prof. Spörer spoke of stormy movements in the atmosphere of the sun. He discussed a long series of details respecting the physics of the sun, which were illustrated by heliographic maps, and emphasised the fact that spots invariably appeared only in very hot luminous regions of the solar surface. Of his theoretical explanations it may be more particularly mentioned that, in the opinion of the speaker, the luminous regions originated in the ascending of gases and vapours from the hot interior of the sun. When such a thing happened at the circumference of the sun, then metallic prominences were observed. In consequence of their higher temperature the luminous regions caused ascending currents, whither cooler gases streamed from all sides. The gases, which in certain circumstances mounted to heights of 30,000 German (135,000 English) miles, cooled, sank as cooler masses endowed with greater linear velocity to the same localities, and there formed the sunspots. In the discussion following this address, Prof. Spörer stated that according to his observations the last maximum had shown itself 1884·0. He further stated that occasionally, under special conditions of illumination, he had, with the aid of the telescope, seen in clouds small, round bodies moving up and down, which he had taken for rain-drops, and commended to those interested in the study of the atmosphere such observations of clouds. Respecting the possibility of seeing the rain-drops of clouds in this manner there arose a lengthy discussion.

Physical Society, November 4.—Prof. von Helmholtz in the chair.—Prof. Spörer produced and made the subject of discussion a long series of heliographic maps which he had drawn from phenomena he had himself witnessed, and which demonstrated in a very graphic manner the occasionally very important proper motions of different spots. These self movements always occurred on the west side of the spots, and of the groups of spots. They always followed therefore in the sense of the sun's rotation. They were recognised when the spots were observed several times in the course of a day, and they sometimes attained values of from 1000 to 2000 geographical miles in one day. These movements were specially intense in the case of the formation of larger spot-groups; later on they grew slower. For the explanation of these proper motions, the speaker adduced that sunspots invariably formed themselves only over luminous surfaces, that is, at spots of the solar surface possessing a higher temperature. In his measurements of temperature, which had not yet been published, having reference to the year 1880, he made use of a thermo-element on which, through a fine opening in a thick pasteboard disk, he caused to fall the position of the sun's image which he wanted to measure. According to these observations, the emission of heat from a spot-umbra stood to the radiation of heat from a luminous surface as 10 : 18, and the radiation of a spot-umbra to the radiation of the usual solar surface as 10 : 15. Seeing that the temperatures on the sun stood probably in the same relation as did the radiations, so in the luminous surfaces which possessed a higher temperature (in the relation of 6 : 5) must an ascending gas-current develop, to which a descent of colder gas-masses must necessarily correspond. These descending colder gases it was which generated the spots, and gave them—seeing they possessed a greater linear speed of rotation than did the solar surface—a displacement towards the west in the sense of the rotation.—Dr. Pernet spoke on the determination of the air in the vacuum of the barometer, in accordance with the Arago method, connecting his observations with a publication by Dr. Schreiber, who, on comparing the barometer of the Saxon station with the normal barometer, found, after taking due account of all corrections in the latter, volumes of air far surpassing the permissible quantities. Dr. Pernet had now found that two very essential corrections were overlooked: first, the determinations of the air in vacuum under the pressures 0, 40, and 80 millimetres, were carried out in much too rapid succession, so that compensations of temperature were impossible; second, the effect of the capillarity was not observed, an effect which in the case of syphon barometers played so far a great part, as the lower surface of the quicksilver affected by oxidation and dust had a different surface-tension and different angles of rim from the upper surface of the quicksilver, which was comparatively pure. The registrations were therefore not exact if the menisci were not simultaneously measured. This tension of the surface was in the case of thermometers also very important. In consequence of it, the readings of thermometers with narrow tube and less mass of quicksilver were less exact than the readings of thermometers with wider tube and more quicksilver. It was the cause that thermometers with elliptic tubes were less exact than thermometers with circular ones. The effect of the capillarity, again, was, in the opinion of the speaker, the cause of the "dead point" of Mr. Pickering.

EXPLORATION OF THE NORTH SEA

Die Ergebnisse der Untersuchungsfahrten S.M.Knbt. "Drache" (Kommandant Korvetten-Kapitän Holzhauer) in der Nordsee in den Sommern 1881, 1882, *und* 1884. Veröffentlicht von dem Hydrographischen Amt der Admiralität. (Berlin: Ernst Siegfried Mittler und Sohn, 1886.)

OUR knowledge of the physical conditions of the North Sea has just been enriched by the publication of the results of the expeditions of the Prussian ship *Drache* during the summer months of the years 1881, 1882, and 1884. The expeditions and the publication have been carried out under the direction and with the authority of the Hydrographic Office of the German Admiralty.

Prof. Möbius, who has examined the organisms collected by the *Drache*, reports that he has found nothing worthy of special mention among the biological collections. It is otherwise with the physical and chemical observations, for the whole of the volume before us is devoted to these observations, their analysis and discussion. The publication is accompanied by synoptic tables showing the positions of the observing stations and the scientific results, as well as by fourteen charts setting forth graphically the currents, the depths, the salinity, specific gravity, and the quantity of oxygen in the surface, intermediate, and bottom water, and sections illustrating the distribution of temperature.

The temperature and salinity are first examined. The observations confirm the view that the salt heavy water of the Atlantic enters the North Sea by the north of Scotland, and, on being cooled, sinks to the bottom, and fills all the deeper parts of the basin, including the Norwegian Gut. The observations of the Norwegians and those on board the *Triton* showed that, in like manner, the deep water of the Norwegian Sea was largely made up of the salt Atlantic water, which sank to the bottom on reaching a colder latitude—probably mixing much with deep colder Polar and fresher water. The *Drache* traced this salt Atlantic water to the centre of the North Sea. It would be a matter of very great interest to have the temperature of the water taken at stated intervals throughout the year in the Norwegian Gut, in a similar manner to the observations now being carried on in the deep lochs of the west of Scotland. The observations on the currents of fresher water running to the north along the coasts of Britain and Jutland—the latter eventually meeting and mixing with that of the Baltic—are very interesting. Indeed, the extensive current and tidal observations are valuable additions to knowledge; but, as the author remarks, both they and the temperature observations are incomplete, being confined to the summer months, and he indicates the regions where observations are much required. Still, combined with the winter observations which we possess at certain points, the *Drache's* observations greatly augment our knowledge of the physical conditions of the North Sea, and of the modifying influences produced by the seasons.

The chemical work has been intrusted to Dr. Neumeister, under the direction of Prof. Jacobsen, and the geological part is by Dr. Gümbel. The chemical work includes the determination of the oxygen and nitrogen in water from different depths. Dr. Neumeister found in surface-water (mean of twenty-five analyses) the oxygen to be 33·95 per cent., the volume of the sum of the oxygen and nitrogen equalling 100. In deep water (200 metres) the oxygen descended to 25·20 per cent. of the volume of the two gases.

For carbonic acid combined as neutral salts, he found for surface-waters 52·66 milligrammes per litre (mean of sixty-seven determinations); the partially combined acid was found to be 43·78 milligrammes (mean of thirty-nine determinations).

As appendix to these researches, the results are given of the determinations of the carbonic acid in the waters of the Atlantic, Indian, and Pacific Oceans, collected by the *Gazelle* in 1874–76. The carbonic acid combined as neutral salts in the surface-waters reaches to 52·5 milligrammes per litre (mean of thirty-one observations). At 183 metres of depth, the mean is 53·2. For greater depths, down to 5000 metres, fourteen determinations gave 50·6 to 56·8 milligrammes. Four determinations gave 59 to 70 milligrammes, and one gave 82·7 milligrammes. No attempt is made to compare these with the *Challenger* results.

The author explains the presence of the large quantity of carbonic acid in deep water by the fact that the water dissolves the carbonate of lime, which is found in great quantity on the bottom in all moderate depths. The carbonic acid which effects this dissolution is probably furnished by the oxidation of organic substances. The author refers to the fact that carbonic acid is not necessary in order that carbonate of lime may be dissolved by sea-water, and has, in this respect, confirmed Dittmar's observations. Different waters, however, comport themselves very differently in this respect. The water of great rivers, adds the writer, at their embouchure contains less acid combined as neutral salts than ocean water, and the mixture of salt and river water, along coasts, less carbonic acid than the water in the great oceans; but the difference is not in proportion to the quantity of salts present. It is shown by analyses of Baltic water that while this water contains only about one-half of the salts present in pure ocean water, it contains nearly nine-tenths of the carbonic acid present in the neutral salts of pure ocean water.

Gümbel's work consists in an examination of the deposits collected from depths ranging from 18 to 317 metres. The forty samples, of which an excellent description is given, all belong to littoral, sub-littoral, or terrigenous deposits. None of them present the essential characters of truly deep-sea or pelagic sediments. The author divides them into quartz sands and sandy clays, the latter being of a much darker colour than the former. Gümbel has followed in his descriptions the methods indicated in the preliminary notices of the *Challenger* deposits. Gümbel attributes the absence of Globigerina ooze from the samples to the relatively shallow depths from which they were procured, and he adds that the depth determines the nature of the deposit. This is quite a mistake: it is, rather, distance from land that determines the kind of deposit. Deposits not unlike those described by Gümbel occur in depths of over 2000 fathoms when near to land, while a Globigerina ooze or Pteropod ooze may occur in very shallow depths, in the tropics, far from land. These deposits of the *Drache*, being near the coast, it is found that quartz predominates. The fragments of plagioclase, orthose, hornblende, augite, bronzite, mica, garnet, tourmaline, dicroite (is it not glaucophane?), magnetite, zircon, chlorite, all come from the disintegration of the ancient rocks which form the coast of Norway and Scotland. Gümbel also finds fragments of granitic rocks, dioritic rocks, &c. Fragments of modern volcanic rocks, such as lavas and pumice, are very rare when compared with the particles derived from ancient rocks. Glauconite was found in some of the specimens, and the author believes that these have been transported, which is quite unlikely, as large deposits of glauconite are now in process of formation along the coasts of the north of Scotland. The organisms—mollusks, echinoderms, foraminifera, and diatoms—are all the same as those usually found in partially inclosed seas like the North Sea, and do not present any peculiarities worthy of note.

The author supposes that there is a continuation under the North Sea of the ancient rock-masses of Scandinavia. This may be true, but the supposition can in no way have been suggested by the chemical, microscopic, and mineralogical examinations of the deposits of the North Sea. In conclusion, Gümbel states that the sediments of the North Sea prove that sandy deposits can be formed alongside of clayey and marly deposits, during the same time in the same sea. This conclusion has already been perfectly established, and this confirmation supports an interpretation generally received, which was one of the first results of the examination of the *Challenger* deposits.

The Hydrographic Office of the German Admiralty have done excellent service in taking up the scientific examination of the North Sea. It is a work that we would like to see continued and advanced by our own Hydrographic Office. J. M.

OUR BOOK SHELF

Chemical Arithmetic. By Sydney Lupton, M.A., F.C.S., F.I.C. Second Edition. (London: Macmillan and Co., 1886.)

We are pleased to note a new edition of this excellent woık, in which several improvements have been made. The hundred pages of introductory matter in the first edition have been reduced by about one-half, much unnecessary pure arithmetic having been cut out. The 1200 examples with answers are, on the whole, well selected, though many of them can scarcely be called chemical. A greater number of typical examples might advantageously have been worked out at full length.

The book is especially to be commended for its clear and concise definitions, which are in many books very loosely expressed. The differences between density and specific gravity, atomic and molecular weights, for instance, are explained in a manner that any student of ordinary ability will readily understand. We feel sure that the book will be appreciated alike by students and teachers, but it will be especially valuable to teachers.

Experimental Chemistry. By C. W. Heaton, F.I.C., F.C.S. New Edition, Revised. (London: George Bell and Sons, 1886.)

Another edition of this work on experimental chemistry, adapted from the German of Dr. Stöckhardt, has just been issued. To those students of limited means who desire to work at chemistry as well as to read it—and it is for those that the book is intended—it will be found useful. The introduction, however, is much too extensive and theoretical for beginners, and we fear that many would be disheartened before reaching the really experimental work. In our opinion, the book is not sufficiently practical, many experiments lacking detail. We would suggest that in future editions a few pages be devoted to instructions in the manipulation of apparatus and the working of glass.

Part IV., which is devoted to organic chemistry, is very clearly set out. The book is not sufficiently modernised for these days of competitive examinations, but the teacher who is desirous of encouraging his students to perform simple experiments in spare moments would get many valuable ideas from it.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Sense of Smell

In your issue of Septhmber 30 (vol. xxxiv. p. 521) your correspondent Dr. Arthur Mitchell is desirous of obtaining some data in regard to the sense of smell. In a paper presented at the Philadelphia meeting of the American Association for the Advancement of Science (1884) we have described a series of experiments designed to test the delicacy of this sense. These experiments, being of a preliminary character, have hitherto been withheld from publication, but the following brief statement of the results obtained may be of interest to Mr. Mitchell and to other readers of Nature. We made use of the following substances:—(1) oil of cloves, (2) nitrite of amyl, (3) extract of garlic, (4) bromine, (5) cyanide of potassium. A series of solutions of each of these was prepared, such that each member was of half the strength of the preceding one. These series were extended by successive dilutions till it was impossible to detect the substances by smell. The order of the bottles containing these solutions was completely disarranged, and the test consisted in the attempt to properly classify them by the unaided sense of smell. The thirty-four observers who assisted in these experiments were of both sexes; the results are indicated in the following table (I.):—

Amount detected

	Oil of cloves	Nitrite of amyl	Extract of garlic	Bromine	Cyanide of potassium
Average of 17 males	1 part in 88,218 of water	1 in 783,870	1 in 57,927	1 in 49,254	1 in 109,140
Average of 17 females	1 part in 50,667 of water	1 in 311,330	1 in 43,900	1 in 16,244	1 in 9,002

The same method of investigation has since been followed by one of us[1] in some experiments, the results of which are given in Table II.

Amount detected

	Prussic acid	Oil of lemon	Oil of wintergreen
Average of 27 males	1 part in 112,000 of water	1 in 280,000	1 in 600,000
Average of 21 females	1 part in 18,000 of water	1 in 116,000	1 in 311,000

[1] "Some Special Tests in Regard to the Delicacy of the Sense of Smell," by E. H. S. Bailey and L. M. Powell (*Proc. Kansas Acad. o Science*, vol. ix.).

Many striking individual peculiarities were noticed in the course of the experiments, which these general averages fail to show. Three of the male observers were able to detect one part of prussic acid in about 2,000,000 parts of water. Two of these were persons engaged in occupations favouring the cultivation of this sense. Careful chemical tests failed to show the presence of prussic acid in several of the more dilute solutions, in which it could be detected by the sense of smell. We found some of both sexes who absolutely could not detect prussic acid even in solutions of almost overpowering strength. There were several instances of the same peculiarity as regards bromine. Again, our averages show that the sense of smell is in general much more delicate in the case of male than of female observers.

Tidal Friction and the Evolution of a Satellite

ADVERTING to the correspondence in NATURE (vol. xxxiv. p. 286), I think that Mr. Darwin has not, so far, fully realised the results that would follow from the circumstance that the Martian satellite's period would be affected many hundred times more than that of the planet's rotation, as explained in the correspondence referred to. He argues that, the moon's mass being great, she should recede to an enormous distance before there will be a reversal of the direction of her tides on the earth; while the satellite of Mars, being very small, need only to recede a short distance before a similar tidal reversal ensues. No mention being made of any other supposed difference in the systems at the starting-point, it must be inferred that other things are supposed about equal. But, as a matter of fact, the present position of the Martian satellite is incompatible with an initial rotation of its planet anything like so great as that ascribed to the earth at a like stage. If Mars be supposed to rotate ten times while the satellite, at its present distance, makes nine revolutions, the satellite's period would still be affected or lengthened much more than would that of the planet's rotation. The difference between the periods of revolution of the planet and satellite would increase quickly at first, but more slowly as the satellite receded a certain distance, till at a certain time there would be no increase, after which there would be a decrease, and finally a reversal. When the satellite would have receded to a short distance, where she would revolve in the same period as Mars now rotates in, the planet would have lost but little of its original rapid rotation. Now, supposing the satellite tide to go round in the same time as the solar one, the period of the satellite would be affected about thirty times as much as that of the planet's rotation. Allowance being made for the comparative slowness of the satellite's tides, the satellite's period would still be changed more than ten times as much as that of the planet. It would be only when the little body got further out, and the planet's rotation slower than it now is, that there could be a reversal of the direction of the satellite's tides. Wherever started, the satellite must either go directly into the planet, or go out a short distance and back into the planet, before the rotation-period can have been much changed by solar tides; or else the satellite must go far out—as when it gets a fair start —and could not possibly turn back until the rotation of Mars be slower than now. Hence it seems that under no conditions could the rotation of Mars, at the birth of her moon, have been twice as rapid as now, and the evidence is very strong that the rotation-period could not have been changed more than a very few hours, if so much. Then, if the rotation of Mars was so slow in the beginning, and so little changed during the whole existence of the satellite, the circumstance does not support the view that the earth's rotation was very rapid in the beginning and so much changed during her past history, but rather inclines the other way.

Respecting the statement that two heavenly bodies cannot revolve about their centre of inertia as parts of a rigid body with their surfaces nearly in contact, unless one be smaller and denser than the other by a certain amount, I can only say, at the present time, that such was the conclusion at which I arrived when investigating the results of the tidal effects of two bodies on one another at close quarters. Without going far into the question, it can be seen that if the rule holds when the two bodies are of the same size and density, it will hold throughout. There will be no difficulty in seeing that the rule holds so far that when the difference in size between the bodies is as great as between any of the satellites and its primary, the small body must be invariably the denser. Now the argument that was supposed to apply in general would at least apply in the case of the solar system. That argument, as explained in my pamphlet, was that, if a rapidly-rotating body were to separate into two, the small body given off must be denser than the other to withstand the tidal disturbance, and that it would be impossible for the small body to be denser than the primary, since the secondary body must be formed from the surface and therefore lightest part of the other body.

JAMES NOLAN

Dergholm, Victoria, October 5

Seismometry in Japan

I HAVE read, with no small surprise, a paragraph in NATURE of November 11 (p. 36), giving a summary of a letter from Prof. John Milne, with reference to an article by me on the seismographs now manufactured by the Cambridge Scientific Instrument Company. Prof. Milne is represented as saying that, "with the exception of one or two which have been modified, a set of instruments like those recommended by Prof. Ewing are, so far as Japan is concerned, quite obsolete." His letter is not published, and it is possible that the paragraph inadvertently does him an injustice in making him assert what has absolutely no foundation in fact.

In any case the statement cannot be allowed to pass without contradiction. My seismographs have been in regular use at the University of Tokio since they were invented; they are now used for systematic observations by the Japanese Meteorological Bureau; they were sent last year by the Japanese Government to the Inventions Exhibition in London, where they were awarded the highest diploma among Government exhibits: one of them, the comparatively cheap and simple duplex pendulum seismograph, is employed by many private observers in Japan. In a letter received only a few weeks ago, my friend and former assistant, Mr. Sekiya, now Professor of Seismology in the University, says:—

"We are going to start a journal called the *Journal of the Science College of the Imperial University, Japan.* In the first number I will give a paper on 'Comparison of Earthquake Diagrams simultaneously obtained at the same station by two instruments involving the same principle, and thereby proving the trustworthiness of these instruments.' Of course I treat those diagrams recently obtained by two of your seismographs."

Other letters from Prof. Sekiya are full of accounts of the excellent work he is doing with these instruments, and of their continued and extended usefulness in his very able hands. A paper lately received from him describes a rough but effective form of the duplex pendulum, cheaply made in order to bring it within the reach of private observers, and with reference to this the *Japan Mail* of February 2, 1886, says:—

"The duplex pendulum seismograph designed by Prof. J. A. Ewing, has been employed for earthquake observations in the Tokio Daigaku by Mr. S. K. Sekiya, who has improved many of its details during his long use of the instrument. On account of the simplicity and scientific nature of its construction, and its easy management, it has found its way into the hands of many observers."

The *Mail* goes on to mention the name of a native firm by whom the instrument is made and sold. In March last Mr. Sekiya writes:—"The duplex pendulum sells well; some fifteen or twenty of them have been sold."

So much for the duplex pendulum seismograph, which is one of those described in my article, and now made with the utmost refinement of construction by the Cambridge Company. The other is a three-component instrument, of which the principal part is the horizontal pendulum seismograph—consisting of a pair of horizontal pendulums for recording separately two rectangular components of the horizontal motion of the ground on a moving surface driven by clockwork. This method of recording earthquakes was introduced by me in 1880 (*Trans. Seis. Soc. Jap.*, 1880; *Proc. Roy. Soc.*, No. 210), and has been in regular use ever since. The instruments made to my designs by native workmen are still doing good service in Prof. Sekiya's hands. Those now made by the Cambridge Company have the advantage of better workmanship and an improved arrangement of parts. As Prof. Sekiya has recently written to me with regard to the purchase of a set of them by the Japanese Government, it is probable that Mr. Milne will before long have an opportunity of seeing the latest forms of the instruments in Japan.

No one knows better than Prof. Milne that the horizontal pendulum seismograph is not obsolete. He adopted it himself soon after I introduced it, and he has used it freely in his own investigations. His letter will be understood to mean that since I left Japan in 1883 there has been a new departure in seismometric methods which has made my apparatus fall out of date. There has been nothing of the kind. Can Mr. Milne point to any methods involving novel features of importance, and say what their novel features are? It would be odd for instruments to become obsolete when they answer their purpose very well, and when there is nothing better to take their place.

University College, Dundee, November 13

Ozone Papers in Towns

I take the opportunity of mentioning that I have experimented with Moffatt's ozone papers in London for the past month, and find that on exposing the papers already previously coloured they all become bleached to their original white. They were previously exposed to the air at Brighton and Hastings, on the sea-coast, and were then coloured, and afterwards preserved closely shut up for trial in the mephitic air of towns.

Some more stained papers were also received from Cheltenham, which also became blanched on open-air exposure in London, though as highly stained as 8 degrees. They were not washed by rain, but kept dry in the usual cage in the open air and out of the sun; and they were of various shades of colour, from 2 to 8, as already marked on them. I should like to know or ask for opinion as to the chemical changes that had taken place, and if these had been due to an antozone causing a recomposition of the ingredients (starch and iodide potassium) to their original constitution. It may be likely, therefore, that in Moffatt's papers, coloured previously, we may have the means of testing the impure condition of the air of any locality by exposing them in it for a few hours.

Other papers had already been prepared for testing the sulphurous impregnation of the town air, as by compounds of lead, tin, &c.; but, though they became stained in the laboratory, yet they failed on trial in the open air. As to the influence of the wind, the quickest effect seemed to be produced by easterly winds, while those from the south-westerly direction were slower in action on the papers; but this, I think, may be merely due to the air from the east in London blowing first over a greater expanse of city, carrying with it adulterating emanations.

London, November

The Similarities in the Physical Geography of the Great Oceans

In the abstract of my paper read at the Royal Geographical Society on the 8th inst., which was published in Nature of Nov. 11, there is a statement (p. 34) that the weight of the column of water between 20 fathoms and 70 fathoms from the surface under the westerly equatorial current is only 88 per cent. of the weight of the same column under the easterly counter equatorial current. I regret that a serious arithmetical error occurs in the calculations on which this statement was founded. There is no such considerable difference of weight in the two columns of water.

Edinburgh, November 22

Lung Sick

Dr. E. J. Dungate, with compliments to the Editor of Nature, begs to inclose him a letter which he has just received from Prof. Smets, of Hasselt. It refers to the letter on "lung sick," which appeared in Nature for November 11 (p. 29), and contains most important evidence on the subject. Dr. Dungate is sure, from the genial tone of the letter, that the Editor of Nature is at liberty to publish it, if he desires.

6, Marchmont Road, Edinburgh, November 17

Hasselt (*Belgique*), *le* 14 *Novembre*, 1886

Monsieur Dungate,—J'ai lu votre demande dans la Nature du 11 Novembre.

L'inoculation préventive de la pleuropneumonie exsudative a commencé à Hasselt, et la méthode, suivie déjà chez les Zoulous, a été préconisée, en premier lieu, par un médecin de Hasselt, M. le Dr. Willems. Je vous communiquerai, avec plaisir, ses travaux si vous les désirez.

On a essayé, à diverses reprises, à Hasselt, les inoculations au fanon, à la poitrine, etc.; elles ont eu des conséquences mortelles.

Je crois que cette pratique permettait au microbe d'envahir rapidement les poumons, et d'étouffer le bœuf. Mais quand on pratique l'inoculation à la queue, le microbe a passé par les divers stades de son existence, et est déjà à son déclin avant d'arriver au poumon. Il est possible aussi que le microbe, que je crois fortement aérobie, a été atténué dans sa virulence par suite de son passage dans des organes où l'oxygène est plus rare

Plusieurs fois, néanmoins, l'inoculation est encore mortelle, en moyenne 1 cas sur 100 inoculations à Hasselt.

La perte de la queue est due, à mon avis, à ce que l'on fait usage d'un virus impur, obtenu empiriquement, sans culture. La gangrène, qui emporte une partie de la queue, peut être causée par un autre organisme inoculé simultanément avec le microbe de la maladie. Car, parfois, plusieurs bêtes inoculées en même temps, avec le même virus, ne perdent pas la partie inférieure de la queue, tandis que d'autres fois cet accident est fréquent. On prévient partiellement cet accident en faisant des incisions longitudinales dans l'engorgement qui se produit.

Agréez, Monsieur Dungate, l'expression de ma considération distinguée et de mon entier dévouement.

Dr. Gérard Smets,
Professeur à Hasselt (Belgique)

Meteor

Passing along Kensington Gore yesterday at 7.20 p.m., I saw the finest meteor I have ever seen in my life. It descended from near the zenith perpendicularly through the constellation of the Great Bear. It was much larger than any planet. About half-way on its downward course it gave out a second meteor of a red colour, being itself of a pale yellow. The atmosphere was rather foggy at the time, but I could see the stars through the mist. It was, no doubt, the same meteor as is mentioned in to-day's *Times* as having been seen at Reading.

P. L. Sclater

3, Hanover Square, London, W., November 18

The Origin of Species

Mr. Catchpool, writing in Nature (vol. xxxiv. p. 617) on this subject, says:—"If B is separated from A by being nearly infertile, and C from B in the same way, C is likely to be still more infertile with A." This is quite a mistake. Suppose B to be the cat species, and A and C two varieties of dogs; A and C are quite fertile with each other, and infertile with B.

It is certain that mutual infertility is not caused by mere visible unlikeness. The horse and the ass, which do not produce fertile offspring, are much less visibly unlike than many of the varieties of dogs or of pigeons, which are mutually quite fertile.

May not mutual infertility be a result of long-continued separation, quite independently of any unlikeness arising? I do not know whether this conjecture is supported by any observations on the mutual relations of kindred species or varieties in lands separated by oceans.

Joseph John Murphy

Belfast, November 8

Mr. Murphy has mistaken my meaning, which I will try to make clear by an example. Suppose one brood of an ancient species of Gallinæ to have exhibited, as a sport, a partial infertility with the rest of the species, while the birds composing the brood remained abundantly fertile among themselves. Suppose the main body of that species to have become, by natural selection, our pheasants, while the isolated brood became the ancestors of our grouse. Suppose one brood of these grouse to have become partially infertile with the main body of grouse, and to have been the ancestors of our red grouse, while the main body of the grouse became, by natural selection, our black grouse. If, as I believe, variation does not produce or increase infertility, the black grouse will still be only partially infertile with the pheasant, and the red only partially infertile with the black grouse; but it seems probable, *primâ facie*, that the second spontaneous infertility would remove the red grouse further from the pheasant, so that these would be quite infertile. But this is merely argument from analogy; there is no evidence of the result of such superposed "sports," and retrogression to greater fertility seems possible.

This instance is not a good one, because the observed partial infertility (*i.e.* only occasional fertility) between pheasant and black grouse may be due to dislike, not partial impotence. But I doubt whether distaste for pairing and impotence when paired are often quite dissociated.

Mr. Murphy asks, as I asked in these pages in 1884, and others have asked since, for one simple fact which would be decisive. Is it, or is it not, the fact that allied species which are confined each to a particular island, prove, when brought together, far less frequently infertile than species, equally dissimilar, which had lived in the same district, might be expected to prove. On the answer to this question depends, as far as I can see, the fate of the theory of physiological selection. Can no one answer it?

EDMUND CATCHPOOL

THE CORAL REEFS OF THE SOLOMON ISLANDS [1]

OUT of a collection of nearly seventy corals which I made in these islands, nearly a quarter are new or undescribed; and from this fact, as I am informed by Mr. S. Ridley, it may be inferred that there is yet much to be learned of the corals of this region. After describing in my paper the characters of a typical reef, I proceeded to refer to the complex relations that exist between the multitudes of creatures that frequent coral reefs. The protective colouring of the small crabs that live among the branching corals often attracted my attention. I recall, in particular, the instance of a small crab that finds its home among the branches of a *Pocillopora*. The light purple colour of its carapace corresponds with the hue of the coral at the base of the branches, where it lives; whilst the light red colour of the big claws, as they are held up in their usual attitude, similarly imitates the colour of the branches. To make the guise more complete, both carapace and claws possess rude hexagonal markings, which correspond exactly in size and appearance with the polyp-cells of the coral. Another species of crab, that climbs about the blue-tipped branches of a *Madrepora*, has the points of its pincer-claws similarly coloured. It is interesting to note that these two crabs are adapted to live each on its own species of coral. Had I caused them to exchange their homes, their borrowed hues and markings would have at once made them conspicuous objects for their enemies.

I paid especial attention to the inter-tidal exposure of living corals, and was much surprised at the number of species which are bared by the ebbing tide. Of all the corals in these islands, those belonging to the genus *Cœloria* seem to be the hardiest in this respect. In the paper I have described my observations with some detail.

Coral Reefs and Shoals.—The earliest condition of the coral reefs in this group is to be found in that of the numerous detached submerged reefs or shoals which lie below the limit of the constructive power of the breakers, having been arrested in their upward growth at depths varying between 5 and 10 fathoms according to the exposed or protected character of their situation. This remarkable fact of the arrest of the upward growth of the coral at these depths was utilised by Lieut.-Commander Oldham whilst surveying these submerged reefs in H.M.S. *Lark*. If a shoal was not marked at the surface by a reef-flat or by an islet, we could sail over it with perfect safety. The broken water of the tide-rip that indicated these shoals was no source of danger for a vessel of light draught. In my paper I have given evidence to prove that a shoal which was found by Bougainville in 1768 to be covered by 5 fathoms, remains in the same condition at the present day. The number of coral shoals possessing these characters led me to the conclusion that isolated submerged reefs are unable without the assistance of a movement of elevation to raise themselves to within the constructive power of the breakers. When they have reached their upward limit, they extend laterally, forming ultimately flat-topped shoals. It may appear bold to suggest that atolls and barrier-reefs owe their appearance at the surface to a movement of elevation; but we know that in the regions occupied by the atolls of the Low Archipelago, of the Fiji Islands, and of the Pelew Group, the last movement experienced has been one of elevation; whilst the observations of Mr. Beete Jukes on the Australian Barrier-Reef go to show that, if there has been a recent change of level in that region, it was one of the same nature. In the atoll of Oima in the Solomon Group I found evidence of an anterior elevation.

[1] Abstract of a Paper by H. B. Guppy, M.B., late Surgeon H.M.S. *Lark*. Communicated by Dr. John Murray to the Royal Society of Edinburgh on July 5, 1886.

In my paper I proceeded to describe at some length the reefs that have reached the surface. In this abstract, however, I can only refer to the fact that all the three classes of reefs are to be found in this group; the atolls, I should add, being comparatively few in number and of small size.

The Formation of Atolls.—My observations go to show that atolls of small size (a mile or two across) do not assume their characteristic form until they have reached the surface. After upheaval has brought a submerged coral shoal within the constructive power of the breakers, it soon appears at the surface as an isolated patch of reef. Extensions or wings grow out on either side, and, guided by the prevailing currents (in the manner described by Semper), they ultimately form the common horse-shoe reef, which presents its convexity against the currents. Large atolls evidently begin to assume their characteristic shape below the surface as described by Murray and A. Agassiz.

The Formation of Barrier-Reefs.—The facts on which my conclusions have been based were obtained by the examination of the weather slopes of reefs. For the first 70 or 80 yards from the weather edge of a reef there is a gradual slope, largely bare of living coral, to a depth of 4 or 5 fathoms. There is then a rapid descent to a depth varying between 12 and 18 fathoms. It is this declivity that constitutes the growing edge of the reef, and the sand and gravel produced by the constant action of the breakers collect at its foot. When the submarine slope is more than 10° or 12°, as is usually the case, the sand and gravel extend far beyond the depths in which reef-corals thrive; but when the slope is gradual, *i.e.* less than 5°, the lower margin of this band of detritus lies within the reef-coral zone, and in consequence a line of barrier-reef is ultimately formed beyond this band with a deep-water channel inside (*vide* diagram). Should the

Barrier-reef of Choiseul Bay (drawn on a true scale to the 100-fathom line. *a* = incipient barrier-reef (size purposely exaggerated); *b* = belt of sand and gravel.

area be undergoing elevation, a succession of concentric lines of barrier-reefs will originate, line after line being advanced as fresh portions of the sea bottom are brought towards the surface, each line growing upward along the lower margin of the band of detritus derived from the line of reef inside it. In such a manner have the Shortland Islands been produced. When I arrived at the above conclusion I was not aware that substantially the same explanation had been advanced thirty years before by

Prof. Joseph Le Conte in the instance of the Florida reefs. He then pointed out that since corals will not grow on muddy shores or in water upon the bottom of which sediment is collected, the favourable conditions can only be obtained at some distance from the shore, where a barrier-reef would ultimately be formed *limited on one side by the muddiness and on the other by the depth of the water.*

The foregoing conditions may be described as the determining causes of a barrier-reef. After the reef has been formed, the lagoon-channel will be kept open by such agencies as solution, diminished food-supply, tidal scour, organic degradation, and other influences The circumstance that barrier reefs are frequently situated at or near the borders of submarine plateaus receives a ready explanation in the view first advanced by Prof. Le Conte, since in such situations the necessary conditions of depth and clearness would be found.

Anomalous Depths of some Atolls and Barrier-Reefs.—One of the principal arguments in favour of the theory of subsidence lies in the assertion that lagoons and lagoon-channels are sometimes deeper than the reef-coral zone. I will, however, endeavour to show that this assertion is founded on a misconception of the conditions that limit the depth of this zone. The extent to which the depth may vary is demonstrated in the great divergence between the estimates of different observers in every region of coral reefs. Those of Quoy and Gaimard, Ehrenberg, Darwin, Dana, Murray, A. Agassiz, and others, range from 5 to 40 fathoms. But this variation may also be found in the same region of coral reefs. Thus, in the Solomon Islands, I found that the depths at which reef-corals flourished ranged in different localities from 12 to 40 fathoms and beyond, the variation being due to differences of local conditions, such as the degree of inclination of the submarine slope, the presence and position of submarine declivities, the amount of sediment held in suspension, the force of the breakers, and other influences. The main determining condition, as Prof. A. Agassiz points out, is to be found in the injurious effect of sand and sediment rather than in the general influence of depth; and the distribution of these materials is dependent on the local conditions above referred to. Local conditions will usually restrict the reef-coral zone to depths less than 30 fathoms; but, where there is a gradual submarine slope, reef-corals are to be found in depths beyond the sand and gravel. Inasmuch as most observers have regarded these materials as necessarily limiting the zone, they did not push their inquiries beyond. Under favourable conditions, however, reef-corals may thrive in depths of 50 or 60 fathoms; and thus we can readily explain the apparently abnormal depths inside some atolls and barrier-reefs.

An apparent objection here presents itself. If reefs begin to build their foundations in depths greater than those which are generally assigned to them, the thickness of the elevated reef-formations discovered by me in the Solomon Group should have been much greater than 150 feet, the actual limit of their thickness. It will, however, have been gathered from the previous remarks that local conditions will usually confine reef-corals to depths less than 25 or 30 fathoms, and that it will be only under occasional circumstances that reefs will commence to be formed in deeper water. Fringing-reefs themselves are at first restricted to shallow waters around the coast, and their seaward extension in localities where the submarine slope is at all steep, as is generally the case, must be extremely slow. Again, in an area of elevation, such as that in which the Solomon Islands are included, barrier-reefs, which may have begun to grow in depths not less than 50 fathoms, might owe their approach towards the surface as much to the elevating movement as to the very slow upward growth of the corals. It should also be borne in mind that the rapid subaërial denudation, to which these regions of heavy rainfall are subjected, would be an important agency in the thinning away of the raised coral formations.

In the latter part of my paper I refer, amongst other subjects, to the extensive character of the degradation of coral reefs by multitudes of organisms. I also give proofs of the outward growth of reefs on their own talus (as described by Murray)—(1) in the circumstance that massive corals may be commonly observed to increase in size as one approaches the lagoon from the outer margin of the reef-flat; (2) in the presence of old lines of erosion evidently produced at the existing sea-level, but which have been cut off from the action of the waves by the advancing edge of the reef-flat; (3) in the characters and position of the wooded islets situated on reefs, which in course of time would cover the whole reef-flat, were it not for one counteracting circumstance, the seaward growth of the reef.

Lastly, I refer to the deposits at present forming on the outer slopes of reefs in depths down to 100 fathoms. Reef-debris, foraminiferous tests, especially of *Orbitolites*, joints of the calcareous alga *Halimeda opuntia*, portions of *Nulliporæ*, and the small detached corals of the genus *Heteropsammia*, enter largely into the composition of these deposits. I should add that a rock of this composition is one of the commonest types of the so-called coral limestones in the Solomon Group.

In this short abstract of a long paper I have not been able to do much more than indicate the general bearing of my conclusions. The facts and data are given at length in the original paper.

THE BRITISH ASSOCIATION AND LOCAL SCIENTIFIC SOCIETIES

THE second annual Conference of Delegates held under the new rules of the British Association met at Birmingham on September 2 and 7, in the library of the Medical Institute. Forty-nine local Societies carrying on work in various parts of the United Kingdom have been enrolled this year as "Corresponding Societies" of the Association, and of these thirty-two were represented by Delegates at the Birmingham meeting. The following report of the proceedings of the Conference, signed by Mr. Francis Galton and Prof. R. Meldola, the Chairman and Secretary of the Committee, has just been circulated among the Corresponding Societies, and it will be seen that this new branch of the work of the Association promises to be of mutual advantage both to the Societies and the Association:—

At the first Conference the chair was taken by Dr. A. W. Williamson, F.R.S., General Treasurer of the British Association, the Corresponding Societies Committee being represented by Captain Douglas Galton, F.R.S., General Secretary of the Association, Dr. Garson, Mr. John Hopkinson, F.L.S., and Prof. R. Meldola, F.R.S., Secretary.

The Secretary read the Report of the Corresponding Societies Committee which had been presented to the Council of the Association.

The Chairman made some remarks explanatory of the objects of the Conference of Delegates, and suggested that among other subjects of investigation in which it might be useful to secure the co-operation of the local Societies was that of injurious insects, already so much studied by Miss E. A. Ormerod.

The Secretary also made some observations in explanation of the constitution of the Corresponding Societies Committee and the relations existing between the Conference of Delegates and the British Association.

Some remarks were made by Mr. J. W. Davis and others with reference to the advisability of securing the co-operation of the local Societies for the purpose of investigating British Barrows and other prehistoric remains. This suggestion had been put forward at the Aberdeen Conference last year by Prof. Meldola, and a Committee was about to be formed by Section H for carrying out this object.

Mr. H. Heywood considered that the relationship now existing between the British Association and the Corresponding Societies had already been of great assistance to the Societies themselves. In the case of his own Society (Cardiff) they had been able to assist one of the Committees (Erratic Blocks) brought under the notice of the Aberdeen Conference last year.

Prof. Lebour stated that many of the local Societies, such as the North of England Institute, which he represented, were composed of engineers connected with large works, who might make useful investigations which would be facilitated if backed up by the authority of the British Association. For this reason he hoped that other subjects besides natural history, geology, or anthropology would be recognised at the Conferences.

Captain Galton explained that the object of the Conference of Delegates was to bring the Corresponding Societies into direct communication with *all* the Committees of the British Association, to which the local Societies or individual members of these might render assistance. This could of course be only effected by degrees, but he suggested that as a preliminary step it might be found useful to place the Delegates on the Committees of those Sections in which they or their Societies had the most interest.

Dr. Williamson supported this proposition, and the Secretary took down the names of the Delegates to be attached to the various Sectional Committees.

Prof. Hillhouse and Dr. Garson expressed their willingness, as Secretaries of Sections D and H respectively, to propose Delegates as members of the Sectional Committees.

Mr. Hopkinson suggested that among other methods of promoting work among local Societies it might be found advantageous for the Delegates themselves to make suggestions at the Conference which might lead, through the proper channels, to the formation of new Committees by the British Association. He stated that his own Society (Hertfordshire) had already rendered material assistance to the Erratic Blocks Committee of the Association, and they hoped to render similar service to the Underground Waters Committee.

The following resolution, framed with the object of keeping the Corresponding Societies informed of the work being done by the British Association Committees, was moved by Dr. Garson, seconded by Captain Galton, and passed unanimously:—

"That the Secretary of the British Association be requested to send a list of the several Committees appointed by the Association to each of the Delegates of the Corresponding Societies, or to the Secretaries of these Societies, as soon as possible after the meeting of the Association, together with a copy of the proceedings of the meetings of the Conference of Delegates."

At the second Conference the chair was taken in the absence of Dr. Williamson by Prof. Boyd Dawkins, F.R.S., the Corresponding Societies Committee being represented by Dr. Garson, Mr. John Hopkinson, F.L.S., and the Secretary, Prof. R. Meldola, F.R.S.

The Secretary read the minutes of the proceedings of the first Conference, and it was stated that in accordance with the decision then arrived at the Delegates had been placed on the respective Sectional Committees as "Delegate Members."

The Chairman directed attention to the kind of work which might be done at the Conferences, stating that as a member of the Council of the British Association he knew that the Association was anxious to consolidate the work of the local Societies. He suggested that the best mode of procedure would be to take the different Sections *seriatim*, and hear the recommendations forwarded by the Committees of these Sections, together with suggestions by the Delegates respecting the lines of investigation in which the local Societies could take part.

SECTIONS A AND B.—No recommendations from the Committees of these Sections having been forwarded to the Secretary of the Conference, the Chairman invited suggestions from the Delegates.

Luminous Meteors.—Mr. F. T. Mott suggested that much useful work might be done if the local Societies would undertake to record systematically the appearance, position, direction, &c., of luminous meteors.

The Secretary stated that a Committee of the British Association was for many years in existence for the purpose of carrying out these observations, but, for some reason unknown to him, the Committee appeared now to have ceased its labours.

Magnetic and Tidal Observations.—Mr. J. Martin White suggested that some of the local Societies which were favourably situated for the purpose might undertake systematic observations of local tidal and magnetic phenomena.

Meteorological and Phenological Observations.—Mr. Heywood stated that many valuable meteorological observations were buried in the log-books of steamships, and suggested that some of the local Societies might render good service to meteorology by examining these books and keeping records of any important entries. Mr. Hopkinson pointed out two ways in which the local Societies might advance meteorological science. In the first place he thought that many observers in different parts of the country might be in the habit of recording the rainfall or other meteorological phenomena without communicating the results to Mr. Symons. Good service would be rendered if the Corresponding Societies would find out such observers and put them into communication with Mr. Symons.[1] In the next place he suggested that observations of the time of flowering of plants, first appearances of birds and insects, &c., might be systematically recorded and forwarded to the Royal Meteorological Society by those observers who had not hitherto been in the habit of communicating their results to that Society.

SECTION C.—Mr. C. E. De Rance, F.G.S., attended the Conference on behalf of the Committee of this Section. The three following recommendations were forwarded by the Secretary of the Section:—

Sea Coasts Erosion.—"That Messrs. R. B. Grantham, C. E. De Rance, J. B. Redman, W. Topley, W. Whitaker, and J. W. Woodall, Major-General Sir A. Clarke, Admiral Sir E. Ommanney, Sir J. N. Douglass, Captain J. Parsons, Captain W. J. L. Wharton, Prof. J. Prestwich, and Messrs. E. Easton, J. S. Valentine, and L. F. Vernon Harcourt be reappointed a Committee for the purpose of inquiring into the Rate of Erosion of the Sea Coasts of England and Wales, and the influence of the Artificial Abstraction of Shingle or other Material in that Action; that Messrs. De Rance and Topley be the Secretaries."

Underground Waters.—"That Prof. E. Hull, Dr. H. W Crosskey, Captain Douglas Galton, Prof. J. Prestwich, and Messrs. James Glaisher, E. B. Marten, G. H. Morton, James Parker, W. Pengelly, James Plant, I. Roberts, Fox-Strangways, T. S. Stooke, G. J. Symons, W. Topley, Tylden-Wright, E. Wethered, W. Whitaker, and C. E. De Rance be reappointed a Committee for the purpose of investigating the Circulation of the Underground Waters in the Permeable Formations of England, and the Quality and Quantity of the Waters supplied to various towns and districts from these formations; and that Mr. De Rance be the Secretary."

Erratic Blocks.—"That Profs. J. Prestwich, W. Boyd Dawkins, T. McK. Hughes, and T. G. Bonney, Dr. H. W.

[1] G. J. Symons, F.R.S., 62, Camden Square, London, N.W.

Crosskey, and Messrs. C. E. De Rance, H. G. Fordham, J. E. Lee, D. Mackintosh, W. Pengelly, J. Plant, and R. H. Tiddeman be reappointed a Committee for the purpose of recording the position, height above the sea, lithological characters, size, and origin of the Erratic Blocks of England, Wales, and Ireland, reporting other matters of interest connected with the same, and taking measures for their preservation; and that Dr. Crosskey be the Secretary."

Mr. De Rance described the above three inquiries undertaken by Section C, in which it was thought the Corresponding Societies could render valuable assistance. Forms of inquiry had been circulated largely by these Committees, and it was suggested that any work done by the Corresponding Societies should be on these forms printed by the British Association. Mr. De Rance stated that forms would always be supplied to the Secretaries of Corresponding Societies applying for them.

Dr. Crosskey made some remarks explanatory of the work of the Erratic Blocks Committee. He stated that the assistance of the local Societies would be particularly valuable in this inquiry, and that he would be happy to supply the necessary forms to the Corresponding Societies in the hope that they would be filled up. He urged upon the Delegates the necessity for preserving these boulders, which were everywhere being broken up, and were rapidly disappearing from off the face of the country.[1]

Earth-Tremors.—Prof. Lebour stated that for some time past the North of England Institute of Mining and Mechanical Engineers had had a Committee actively engaged on the subject of earth-tremors and their possible connection with mine-explosions. This subject was naturally related to those of Sections A, C, and G of the British Association, and its investigation might be powerfully promoted by them. Some of the Corresponding Societies might aid greatly in making and recording observations on earth-tremors in various parts of the country. The more extensive the area over which such observations were made (if by competent observers and with suitable instruments) the more valuable they become; but it was very important that there should be some general understanding between the observers in different parts of the country, in order that some degree of that uniformity which is so desirable in matters of this kind should be attained. The cost of the expensive instruments necessary would be much lessened if large numbers of them were used. The question of earth-tremor observations was only one of many in which the engineering Societies and the British Association could be mutually useful, the former carrying out the work and the latter lending the influence of its official recognition and support.

The Rev. J. M. Mello stated that colliery proprietors were generally unwilling to spend money in investigations unless some very specific form of inquiry was circulated.

Mr. Hopkinson remarked that the Corresponding Societies, if supplied with the necessary forms, would no doubt be willing to circulate them among their members. Mr. Heywood thought the suggestion for observing and recording earth-tremors a most valuable one, and he remarked that the Cardiff Society would be happy to assist in the investigation if the formation of a Committee was sanctioned by the Association.

SECTION D.—The Committee of this Section was represented by Prof. W. Hillhouse, M.A., F.L.S.

Preservation of Native Plants.—In reply to a question by the Secretary, Prof. Hillhouse stated that in response to the inquiries which he had circulated among the Delegates and others likely to furnish information, he had received details from twelve or fourteen localities recording between two and three hundred disappearances of plants. Mr. Stirrup stated that for years past a great destruction of plants had been going on in the Manchester district, and the local Societies had found it necessary to strongly inculcate among their members the necessity of preventing this extermination. Mr. Hopkinson remarked that a similar rule had been always observed by the Hertfordshire Society with respect both to animals and plants, and he thought that all the local Societies should adopt it. Mr. Mott pointed out that one practical result illustrating the benefit of Prof. Hillhouse's resolution had been the omission of the localities of all the rare ferns and orchids from the flora of Leicestershire, which his Society was just about to publish.

Local Museums Committee.—Mr. Mott stated that a joint Committee, composed of representatives of Sections C and D, had been recommended for appointment for the purpose of reporting upon the provincial museums of the United Kingdom. The work of this Committee would be much facilitated by the co-operation of the local Societies, and he hoped that the Delegates would bring the matter under the notice of their respective Societies. The Committee consists of Mr. V. Ball, Mr. H. G. Fordham, Profs. Haddon and Hillhouse, Dr. Macfarlane, Prof. Milnes Marshall, Mr. Mott (Secretary), Dr. Traquair, and Dr. Henry Woodward.

In reply to a question as to whether the work of this Committee was to be confined to public or to extend to private museums, Mr. Mott stated that it might be found desirable to extend the report to some few private museums.

The Chairman remarked that the Local Museums Committee was one of the most important that had yet been formed. The local museums of this country were generally in a most deplorable state, and one of the first things to be done was to exclude from such collections all extraneous specimens that were not truly local. According to his experience, he had found that it was impossible for a local Society to flourish and at the same time to carry on a large museum successfully. The two organisations should be independent, but at the same time it was most desirable that the objects collected by local Societies should be handed over to the nearest local museum. With reference to this question of local museums, he considered that we in this country were much behind Germany, America, and France.

A short discussion took place with reference to the naming of specimens in local museums, in which Mr. Eve, Mr. Hopkinson, and the Chairman took part.

SECTION H.—The Committee of this Section was represented by Dr. Garson, who stated that one Committee which was about to be formed on the recommendation of their Section had arisen from the suggestion made by Mr. J. W. Davis at the last Conference.

Prehistoric Remains.—The following is the resolution sent up to and adopted by the Committee of Recommendations:—"That Sir John Lubbock, Dr. R. Munro, Mr. Pengelly, Prof. Boyd Dawkins, Dr. Muirhead, and Mr. J. W. Davis be appointed a Committee to ascertain and record the localities in the British Islands in which evidence of the existence of prehistoric inhabitants of the country is found."

Prof. Meldola stated that three years ago he had brought this subject under the notice of the Delegates in a paper which he had read at the Southport meeting of the Association, and which had been published in abstract in the volume of Reports for 1883, and *in extenso* in the *Transactions* of the Essex Field Club.[1] He remarked that the work which the Committee proposed to undertake was of the greatest national importance in view of

[1] The addresses of the Secretaries of these three Committees are:—
Underground Waters.—C. E. De Rance, F.G.S., A.I.C.E., 28, Jermyn Street, London, S.W.
Erratic Blocks.—Rev. H. W. Crosskey, LL.D., F.G.S., 117, Gough Road, Edgbaston, Birmingham
Sea Coasts Erosion.—Wm. Topley, F.G.S., A.I.C.E., 28, Jermyn Street, London, S.W.

[1] See NATURE, vol. xxix. p. 19.

the great destruction of ancient remains that had been going on for many years.

The Chairman remarked that the subject was undoubtedly one of great importance, and some of the local Societies had already commenced to record the position of these remains on the Ordnance maps. He stated that according to his experience the 1-inch map could be used, but the 6-inch map would be found much better. One desideratum in the work was a good system of symbols; such a system had been employed in a map of ancient remains recently published in France, and he stated that he should be happy to place this system at the disposal of the Committee. He added that he was glad to be able to announce that he had succeeded in getting an Act passed for the preservation of the ancient monuments of the Isle of Man.

Preservation of Stonehenge.—Dr. Garson stated that the Committee of Section H had forwarded a resolution to the Committee of Recommendations with reference to the preservation of Stonehenge, and, pending its consideration by this Committee, it had been suggested that it should also be brought under the notice of the Corresponding Societies through their Delegates, with the object of these using their influence, as far as possible, for the preservation of this and other monuments throughout the country. The following is the resolution referred to:[1]—"That the attention of the proprietor of Stonehenge be called to the danger in which several of the stones are at the present time from the burrowing of rabbits, and also to the desirability of removing the wooden props which support the horizontal stones of one of the trilithons, and, in view of the great value of Stonehenge as an ancient monument, to express the hope of the Association that some steps will be taken to remedy these sources of danger to the stones."

This resolution had originated last April during a joint meeting of the Geologists' Association and the Hampshire Field Club on Salisbury Plain, when copies were ordered to be forwarded to the proprietor, to the Inspector of Ancient Monuments, and to the Secretary of the Corresponding Societies Committee of the British Association. The proprietor of these valuable remains had hitherto refused to take advantage of the Ancient Monuments Act, though repeatedly requested to do so, neither had he paid due attention to their proper preservation, so that it had been thought desirable to move the foregoing resolution which had been sent to the proper quarter for confirmation by the General Committee of the Association.

Election of Corresponding Societies.—At the termination of the Conference, Mr. Davis raised the question whether a Corresponding Society when once admitted by the Association should not always be retained on the list.

The Secretary explained that the election of Corresponding Societies took place *annually*, and that each of these Societies would be expected to make an annual application for re-election on the printed forms sent out before June. There was no reason why a Society when once elected should not be re-elected every year as long as it kept up its scientific activity. He was of opinion that a failure on the part of a Corresponding Society to send a Delegate to any meeting of the Association should not disqualify that Society for re-election, although it was expected that when a Delegate did attend the meeting of the Association he should be present at the Conferences. Prof. Meldola further stated that some few of the Societies which had been elected last year did not appear in this year's list, the reason being that the Secretaries had not filled in and returned the printed forms sent out at the beginning of the year, nor had any notice been taken of a second application asking whether it was the wish of their Society to be re-elected; so that, as Secretary of the Corresponding Societies Committee, he had concluded that these Societies desired to withdraw, and they had accordingly been removed from the list.

[1] This resolution was adopted by the Committee of Recommendations and confirmed by the General Committee.

THE COLONIAL AND INDIAN EXHIBITION

RESUMING our notes on some of the principal exhibits (NATURE, vol. xxxiv. p. 548), the Court running parallel with and between those of Mauritius and Seychelles on the one side and Cyprus and Malta on the other was that which contained the collection from the

WEST INDIES.

Vegetable products, as might be expected, formed the bulk of the exhibits in this attractive Court, which had an air of comfort and finish not excelled in any other part of the building. Entering the Court from the northern end, the first bay on the left hand was devoted to

Trinidad, an island celebrated both for the quantity and quality of the cocoa grown upon it, which indeed is the staple article of produce. The value of cocoa exported from Trinidad in 1885 is stated in the Official Hand-book to have amounted to 421,974*l.*, and in some "Notes on Trinidad Industries," by Mr. John McCarthy, F.C.S., the Assistant Commissioner for Trinidad, recently published, it is stated that the quantity of cocoa imported into England in 1885 amounted to 10,560 tons, against 10,120 tons in 1884, and 9986 in 1881. Numerous specimens of cocoa seeds are exhibited, as well as prepared cocoa and chocolate.

Mr. McCarthy describes the cultivation of the cocoa-nut (*Cocos nucifera*) as a very profitable industry, though the tree does not bear much before it is eight years old. Experiments, he tells us, "are now being tried in Trinidad to make it act as a shade tree to the cocoa (*Theobroma*)" instead of planting the quick-growing "Bois immortelle." The idea of this planting is to realise from the same land a double crop, namely, that from the *Theobroma* and that from the *Cocos*. It is estimated that seventy trees planted upon an acre of land would, when in full bearing, yield 5000 nuts per annum, which would net, on an average, from 3*l.* to 4*l.* per thousand in Trinidad. The annual import of nuts into London is said to be about 12,000,000, besides which, New York imports enormous quantities, and they are also used to a very large extent for the expression of oil in Trinidad itself. Coffee has also a prominent place in the products of Trinidad, and the plant is stated to thrive well, although it has not yet produced even sufficient coffee for home consumption. More attention has, however, been directed of late to coffee culture in the island, so that it is largely increasing. The cultivation of tobacco is also an industry that promises to become of some importance, and the tobacco is described as being second only to the finest Havana. There is a good exhibit of cigars, which are said to have met with general favour, so that a demand has arisen for them.

Bahamas.—In the Official Hand-book, Sir Augustus Adderley gives a very readable sketch of the history of these islands, and briefly refers to the natural products, foremost amongst which are corals and sponges. He describes the "sponging and wrecking vessels" as fine models and fast sailers, built by the islanders of native hard wood known as "horseflesh," and planked with yellow pine obtained from North Carolina. Conch shells are exported in large quantities to the value of about 1200*l.* per annum, and the pale pink pearls which are found in them to the extent of 3000*l.* per annum. The sponge exports were estimated at 60,000*l.* for 1885. Mention is made of the abundance of plants valued as medicines, many of which might be further developed by systematic trial of their effects in this country. Perhaps the two best known medicinal plants are the Canella Bark (*Canella alba*, Murr.) and the Sweet Bark or Cascarilla

(*Croton Eleuteria*, J. J. Benn.). The first has a bitter, acrid, and pungent taste, and a cinnamon-like smell. With us it is used as an aromatic stimulant, and as a condiment in the West Indies. The sweet bark is a bitter aromatic tonic, formerly used as a substitute for Peruvian bark, but now chiefly as an ingredient in pastilles and for mixing with tobacco for the sake of its pleasant musky odour. The cultivation of perfume-yielding plants is recommended as a probable commercial success, the demand for perfumes at the present time being so great that it has even been proposed to cultivate in Australia on a large scale such plants as are now grown at Grasse, Nice, and Cannes.

Jamaica.—The contents of this Court were both numerous and varied. Rum and sugar were fully illustrated by a large number of samples. Coffee was also well represented; of this article the Official Catalogue states that two distinct classes are produced in the island, the total annual export being about 84,000 cwt. per annum, of which about 10,000 cwt. is Blue Mountain coffee, a fine quality, consigned almost entirely to the Liverpool market. Pimento or allspice is a product exclusively of Jamaica, where it is grown in plantations or gardens known as "pimento walks." The commercial article consists of the dried berries, which were exported from Jamaica to the value of 53,867*l.* in 1885. It is very largely used as a spice as well as in medicine, on account of its aromatic and stimulant properties. The fruits contain a quantity of oil, which is obtained by distillation, and is used in perfumery and for similar purposes to which clove-oil is put. Pimento-sticks are amongst the strongest and best for walking-sticks and umbrella-handles, on account of their strength, rigidity, and non-liability to crack. The pimento-tree is of low growth, and is known to botanists as *Pimenta officinalis*.

In this Court were shown some remarkably fine samples of Annatto seeds (*Bixa Orellana*), noted for their plumpness, as well as for their bright colour, the waxy coating of the seeds being highly valued as a red colouring-matter. A large and interesting collection of fruits preserved in a salt-solution were here shown; amongst others the following will attract attention: Star-apple (*Chrysophyllum Cainito*), Cocoa-plum (*Chrysobalanus Icaco*), Blimbing (*Averrhoa Bilimbi*), Akee (*Cupania edulis*, better known, perhaps, as *Blighia sapida*). Many of these are the produce of introduced plants, and the fruits are for the most part fine examples. Amongst a number of specimens of essential oils from well-known plants, most of which are apparently of excellent quality, are some that are but very little known, such, for instance, as those from the Bermuda Cedar (*Juniperus bermudiana*), the Mountain Cigar Bush (*Hedyosmum nutans*), Mountain Thyme (*Micromeria obovata*), Cigar Bush (*Critonea dalea*), and the Sand Box-tree (*Hura crepitans*).

Barbados.—The exhibits from this island consisted largely of similar produce to the islands already referred to. As illustrating the extent of land occupied by sugar cultivation, it is stated in the introductory notice of Barbados in the Official Hand-book, by the Hon. C. C. Knollys, that "out of a total acreage of 106,470 acres, an area of 100,000 acres is devoted to canes." Tobacco is recommended for extended cultivation, and root-crops such as arrowroot and cassava give heavy returns.

British Honduras.—We take this dependency in this order, as it occupied a position in the Exhibition next that of Barbados. The importance of timber in the produce of British Honduras is seen by a simple glance at the exhibits, and to the future development of these timber resources lies in a very great measure the future prosperity of the colony. In the introductory notes to these exhibits the following paragraph occurs:—"To its timber and dye-woods the colony of British Honduras owes its existence, and whatever measure of progress and advancement it may have attained. To the discovery, first of logwood, and subsequently of mahogany, its original settlement must be ascribed." Notwithstanding the importance of the forest produce, very few of the timbers are yet known either to commerce or to science, but many of them are of exceptional hardness and beauty. Mahogany is, of course, the most important wood in the colony, and, next to it, the cedar (*Cedrela odorata*), which is not only exported to a very large extent, but is also used in the colony for light indoor work—cigar-boxes, trunks, packing-cases, and for dug-out canoes, several of which were exhibited. Amongst a collection of lianes, or climbing-plants, is a specimen of the chew-stick (*Gouania domingensis*), with the singular information, besides that of its use as a tooth-brush and tooth-powder, that "it is used in place of yeast to start fermentation in making ginger- and spruce-beer, &c." Probably the most striking object in this Court is a large and beautifully figured slab of mahogany; the dark wavy cross-markings are extremely beautiful and very remarkable in this wood; the plank is, moreover, without a flaw.

Dominica.—The space occupied by this island, as well as by the remaining colonies, was small; the exhibits on the whole, however, were interesting, and some were worth noting, such, for instance, as the husks or shells of the Liberian coffee, which are said to be worth from 1 to 2 cents. per pound in the United States, the fruits of *Acacia Farnesiana*, stated to be used in tanning, and bark of Guava, the *Psidium Guayava*, which is rich in tannin, and is used as an astringent. Raw lime-juice is exported from Dominica in increasing quantities, but the greater part of the juice is boiled down until ten or twelve gallons are reduced to one, and is shipped in this concentrated form to England and the United States for the manufacture of citric acid.

Montserrat.—Sugar and lime-juice are the principal staples of this island, and these were the most prominent exhibits.

St. Kitts and the Virgin Islands.—From these islands the exhibits were but small, and without special interest.

Antigua.—The chief product of this colony is sugar, the average crop of which for the last twenty years is stated to have been about 12,000 hogsheads. Yams, potatoes, and Guinea corn are also grown in large quantities for native consumption. The exhibits were for the most part such as were shown in other West Indian Courts.

Grenada.—Cocoa is the most important article grown here, and some very fine fruits of good colour were shown, as well as nutmegs (*Myristica fragrans*) custard apples, or bullock's heart (*Anona reticulata*), papaws (*Carica Papaya*), Kola nuts (*Cola acuminata*). These latter were remarkably fine specimens. A good deal of attention, we are glad to see, has recently been paid to its cultivation. The tree exists in all parts of the island, and was introduced in years past by the African slaves, who used to regard it as a specific against intoxication.

Tobago.—The productive resources of this small island are varied, and were well exemplified in the collection of fruits, seeds, fibres, &c. The collection of preserved native fruits in syrup, and jellies prepared from them, was a special feature in this Court, a sample of preserved or candied papaw (*Carica Papaya*) being especially good.

St. Lucia.—Sugar, rum, and molasses are the chief products; cocoa and logwood are also produced in quantities, though the latter is stated to be at the present time a drug in the market. Tobacco, it is stated, has been tried in one district with most satisfactory results, so that it is purposed to extend its cultivation. Neither the individual exhibits in this Court, nor in the remaining one of St. Vincent, call for any special remark. We cannot conclude our notice of the West Indian exhibits without a reference to the series of over 100 water-colour drawings, by Mrs. Blake, illustrative of the flora of the West Indian Islands. JOHN R. JACKSON

Museum, Royal Gardens, Kew

NOTES

THE President and Council of the Royal Society have this year awarded the Copley Medal to Franz Ernst Neumann, of Königsberg (For. Mem. R.S.), for his researches in theoretical optics and electro-dynamics, and the Davy Medal to Jean Charles Galissard de Marignac, of Geneva (For. Mem. R.S.), for his researches on atomic weights. Prof. S. P. Langley was awarded the Rumford Medal for his researches on the spectrum by means of the bolometer. The Royal Medals have, with the approval of Her Majesty, been awarded to Mr. F. Galton and Prof. Guthrie Tait, the former eminent for his statistical inquiries into biological phenomena, and the latter for his various mathematical and physical researches. The medals will be presented at the anniversary meeting on November 30.

MR. CHARLES WILLIAM PEACH, the eminent scientific observer, died in February last, and, not long afterwards, a memorial was addressed to the First Lord of the Treasury, praying that his daughter, Jemima Mary, might, on account of her very slender provision, be placed on the Civil List. The memorial, subscribed by about 140 eminent persons, resulted in a Treasury grant of 200*l.* being sent to Miss Peach, after the expiry of five months. The grant so made being totally inadequate by way of provision, while it fails to denote the high sense entertained of Mr. Peach's scientific services, it has been determined to secure, by private subscription, the means of providing Miss Peach with a permanent annuity. Of the sum necessary to effect this, the Treasury grant of 200*l.* will of course form the nucleus. The Committee believe it is unnecessary to do more than allude to Mr. Peach's more conspicuous services. For half a century he gratuitously supplied to contemporary inquirers the fruits of his research. When Mr. Hugh Miller was engaged in preparing his work on the "Old Red Sandstone," Mr. Peach conveyed to him those specimens from Caithness which materially availed him in illustrating his subject. By his discovery of Silurian fossils in the rocks of Cornwall, he enabled Sir Henry de la Beche, then at the head of the Geological Survey, to obtain a scientific basis for mapping the rocks of Devon and Cornwall. In connection with this important work, also, by his discovery of Lower Silurian fossils in the north-west of Scotland—thereby affording the key by means of which the structure and age of the rocks of the Scottish Highlands must be determined—it was the opinion of Sir Roderick Murchison that Mr. Peach had rendered service such as merited a special recompense from his country. From the Devonian rocks of Cornwall and the Old Red Sandstone of the north of Scotland he procured the fish fauna which supplied a share of the material used by Sir Philip Egerton, Prof. Huxley, and Prof. E. Ray Lankester in preparing their several descriptions. In their monographs, Mr. Darwin and Dr. Carpenter have acknowledged his valuable contributions to a knowledge of the Balanidæ and the Polyzoa, while many other naturalists were also indebted to him for most important zoological observations made along our coasts. Mr. Peach made a valuable collection of the fossils of Brora, Sutherlandshire (Jurassic), now in the British Museum. His discoveries have largely availed in elucidating the fossil flora of the Old Red Sandstone and the Carboniferous rocks of Scotland. In the department of recent marine animals and plants, he has added hundreds of new species to the British lists. In acknowledgment of his scientific acquirements, he received honours from the leading scientific Societies; and in 1875 he was awarded by the Royal Society of Edinburgh one of their gold medals. After twenty-one years of arduous labour in connection with the Coastguard, Mr. Peach was in 1845 transferred by Sir Robert Peel to the Department of Customs, as suggested by the Council of the British Association; but this change, while adding to his leisure, did not materially enhance his emoluments. In the public service his highest income was 150*l.*, his retiring allowance being 130*l.* Such remuneration as he received for his scientific services he applied exclusively to the cause of research. He attained his eighty-fifth year, and in his old age it was a source of deep anxiety to him as to how he should be able to provide for the devoted daughter to whose help and affectionate care he was so much indebted. Five hundred pounds are wanted, and this amount there ought not to be much difficulty in procuring. An account is opened in the Bank of Scotland, for the receipt of contributions, under the care of Mr. Robert Gray, Bank of Scotland, Edinburgh, as Treasurer of the fund. Among the members of the Committee are Sir William Turner, F.R.S.; Sir Joseph D. Hooker; Archibald Geikie, F.R.S., Director-General of the Geological Survey of Great Britain and Ireland; Prof. E. Ray Lankester, F.R.S.; Prof. Tait; John Murray, V.P.R.S.E., Director of the *Challenger* Expedition Commission, Edinburgh; William Pengelly, Torquay; and others.

OUR readers must have noticed the recent telegrams concerning the beleaguered position of Dr. Emin Bey at Wadelai, on the Upper Nile, some 50 miles north of Lake Albert Nyanza. Emin Bey was Governor of the old Equatorial Province of Egypt, and his administration of the province was of a model character. Moreover, he did much before the Mahdi insurrection broke out for the promotion of a knowledge of the natural history and geography of the Upper Nile region, as will be seen from his many communications to *Petermann's Mitteilungen.* His last communication is in the current number of the *Mitteilungen*, and is dated January last. In it, notwithstanding his critical position, he speaks of his collections. When the news of Emin Bey's position first reached this country, the Government regarded it as their duty to do what they could to rescue or succour him, and the Intelligence Branch of the War Office made all inquiries as to routes, among other things taking counsel with Mr. Joseph Thomson. There are many difficulties in the way, especially since the death of Mtesa, King of Uganda; but the Government, we believe, have by no means given up the idea of communicating with Emin Bey. Mr. Stanley has expressed his willingness to lead an expedition, and Mr. Thomson shows, in yesterday's *Times*, how the thing can be done. He believes rightly that the route across Masai Land followed by himself is the directest and shortest, and it is really not necessary to pass through Uganda at all; a sweep could be made round by Lake Baringo and the Suk country, and so westwards 300 miles to Wadelai. Moreover, it seems to us that the route by the west side of the Victoria Nyanza on to the Albert Nyanza is worthy of consideration. Certainly, if Mr. Thomson undertakes to lead a relief expedition, he could accomplish it speedily and peacefully. The English Government is bound to do everything in its power to prevent any disaster falling upon so valuable a life; and if they mean to do anything it ought to be quickly, or else it may be too late.

M. PASTEUR, according to the *Times* Paris Correspondent, exhausted by the incessant labours of the last few years, was to leave on Tuesday, by the advice of his family and friends, for Bordighera, where M. Bischoffsheim has placed his villa at his disposal. The *Times* Correspondent, before his departure, ascertained from M. Pasteur the precise state of the Pasteur Institute subscription and of his experiments. The subscription has now nearly reached 1,800,000f., but contributions still flow in, though rather more slowly, and M. Pasteur has reason to hope that we shall eventually reach the sum required. The Paris Municipality has given a gratuitous lease for 99 years of 2500 metres of ground, the site of the old Collège Rollin. This area being insufficient for the laboratories, not merely for rabies, but for other contagious maladies, he has asked for a lease for 99 years of 2500 metres adjoining, and he expected that this proposal would be acceded to at Monday's sitting. A subscription is being raised among the brewers in England. M. Pasteur then goes on in his communication to describe the results of his operations much in the same terms as in his paper to the Paris Academy epitomised in a recent number of NATURE.

THE following are among the lectures to be given at the London Institution, during 1886-87:—Sir R. S. Ball, F.R.S., Astronomer Royal of Ireland, two lectures on "The Astronomical Theory of the Great Ice Age," one given last Monday, the other for November 29; Prof. E. Ray Lankester, F.R.S., six lectures on "The Elements of Biology," Thursdays, November 25, December 2, 9, 16, 23, 30; Prof. T. W. Rhys Davids, Ph.D., "Buddhism," Monday, December 13; Henry Seebohm, "Birds' Nests and Eggs," Monday, December 20; Eric S. Bruce, "War and Ballooning," Monday, December 27; Dr. C. Meymott Tidy, F.C.S., three lectures (juvenile) on "Chemical Action," Thursdays, January 6, 13, 20; Prof. W. H. Flower, F.R.S., Director of the Natural History Department, British Museum, "Fins, Wings, and Hands," Monday, January 17; Prof. Silvanus Thompson, Ph.D., two lectures on "Electric Bells," Thursdays, February 10, 17; Harold B. Dixon, F.R.S., "The Lighthouse Experiments at the South Foreland," Thursday, February 24. The Thursday lectures will be given at 6 o'clock, excepting on January 27, February 3, March 3, and March 10, when they will be given at 7 o'clock. The Monday lectures are at 5 p.m.

GENERAL J. F. TENNANT sends us the following additional information on the late Major-General John Theophilus Boileau, whose death we announced last week:—"General Boileau was selected to superintend one of the magnetic observatories established by the Honourable East India Company in 1843 in connection with the general scheme of magnetic observatories, and had charge of the Simla Observatory. Long after it was closed for observing purposes he was employed in reducing and publishing the results. He also published a collection of astronomical, magnetical, and meteorological tables, and a set of traverse tables; and possibly some special tables, which, being published in India, have never come into much use, and have practically been superseded by others more recent. General Boileau has long been annually appointed one of the Scrutators at the anniversary meeting of the Royal Society on St. Andrew's Day, and we shall miss there on Tuesday a familiar face and name. His energies and time have long been absorbed in institutions for helping those in want, especially the daughters of officers of the army and soldiers. And now his, in turn, want aid, which an influential Committee is endeavouring to raise for them. Will you lend the aid of your circulation to make known the want among those who can spare?"

WITH reference to the above note we heartily commend to our readers the proposal to raise by public subscription a testimonial in recognition of the devotion displayed by General Boileau over a long period of years in philanthropic works, especially those so ably and successfully carried out by him on behalf of the Royal School for Daughters of Officers of the Army at Bath, and the Soldiers' Daughters' Home at Hampstead. An influential Committee has been formed for giving effect to the proposal, with Field-Marshal the Lord Napier of Magdala, G.C.B., G.C.S.I., R.E., as Chairman, and Major-General Philip Ravenhill, C.B., as Honorary Secretary. It is contemplated that the amount collected will best be expended in purchasing annuities for certain members of General Boileau's family, who are at his death left in very straitened circumstances. The Committee appeal not only to those who are, or have been, connected with either of the two institutions above named, but also to General Boileau's numerous friends and acquaintances, to aid them in attaining the object they have in view. Subscriptions will be received by Messrs. Cox and Co., Craig's Court, London, S.W., by the Honorary Secretary, 50, Holland Road, Kensington, W., or they may be paid to any member of the Committee.

THE *Methodist Times* announces the formation of a "Wesley Scientific Society" for the purpose of promoting intercourse among Wesleyan students of science. It will aim at the encouragement of practical scientific work among amateurs, the guidance of beginners in the study of natural history, the interchange of opinions upon scientific questions, and the collection and circulation of useful facts and observations bearing upon the sciences in general. If sufficient support is promised, the first number of a monthly journal will be issued by next March. The President is the Rev. W. H. Dallinger, F.R.S., and the Secretary is the Rev. W. Spiers, M.A., F.G.S. The Vice-Presidents are Rev. G. Bowden, Rev. N. Curnock, A. C. Graham, M.A., C. W. Kimmins, D.Sc., J. Potts, F.G.S., and Rev. G. S. Rowe. The Rev. Dr. Dallinger, Rev. W. Spiers, and Rev. Hilderic Friend, F.L.S., will edit the Society's journal.

THE great refracting telescope of the Bischoffsheim Observatory is in full operation at Nice. It is second only to the Pulkowa instrument. Observations with it have been conducted most successfully.

ADMIRAL MOUCHEZ, Director of the Paris Observatory, has issued circulars in the name of the Committee for erecting to François Arago a statue on the southern part of the meridian line which passes through that establishment. Subscriptions are received at the Observatory by M. Mouchez. A sum of about 400*l*., which had been collected for a similar purpose when Arago died thirty-two years ago, is in the hands of the Paris Academy of Sciences, and will be placed at the disposal of the Committee.

IT is stated that a subscription will be started at Auxerre, the native place of M. Paul Bert, for erecting a memorial on his behalf.

LAST week a boat containing fourteen persons was successfully worked on the Seine with artificial wings acting on the air, and propelled by a rotating wheel.

DR. FOREL informs us that earthquakes occurred in Switzerland on the following dates:—At Cernetz, Grisons, November 6, 17h. 44m., and at 19h. 59m.; November 7, at 1h. 28m.; over Switzerland, with centre in the Lake of Lucerne, on November 16, 2h. 15m. (all Greenwich times).

WE have received from Mr. J. White, photographer, of Littlehampton, a copy of the last portrait (cabinet) taken of the late Prof. Guthrie. It is a very good one.

DR. R. MULLINEUX WALMSLEY, D.Sc., Senior Demonstrator at the Finsbury Technical College, in the department of Applied Physics and Electrical Engineering, has been appointed Principal of the Technical College about to be established at Kurrachee.

THE decline of the Indian silk industry is a subject which has lately attracted some attention. Various causes have been assigned, such as rack-renting by the Zemindars, while the existence of any specific disease among the silkworms has been strenuously denied. The question seems at last to have been settled by the investigations of a skilled entomologist, Mr. Wood Mason, Curator of the Indian Museum, who, on examining a large number of living cocoons, received from various parts of the country, found over 60 per cent. so diseased that no moths emerged, while such moths as emerged were nearly all sickly and crippled, and only 6 per cent. lived to couple and lay eggs. A further examination showed that the cells of the silk glands, and all other tissues, including even the blood, were in the last stage of disease, and literally crammed with minute corpuscles, identical with those which have been demonstrated to be the cause of the fibrine disease which, in an epidemic form, from 1849 to 1865 ravaged the silkworm nurseries of France, and reduced them to a state of ruin, but which, thanks to M. Pasteur, is now practically eradicated from Europe.

PROF. GIOVANNI LUVINI has just issued, in pamphlet form, a summary of the results of his important experiments on the electric conductibility of vapours and gases. As the readers of NATURE are already aware, these experiments have finally exploded the old theory that the moist atmosphere and other vapours are good conductors. The pamphlet, which is published in Florence, includes an historical survey of the subject, and a full account of the processes adopted by the author. Electricians are reminded that this essay, together with his previous treatise on atmospheric electricity, are merely preparatory to a comprehensive work on the phenomena connected with the aurora borealis, which is now nearly completed.

LIGHTNING-FLASHES have sometimes been observed which, starting from one point, have ended in several. Some remarkable forms of flash have been lately described by Herr Leyst, of Pawlowsk Observatory. In one case a flash went a certain distance in a north-easterly direction, then divided, the two branches forming an angle of about 75°. When these had reached about 35° from each other, they turned and united again to one line. The path of the lightning thus formed a quadrilateral figure. It was further observed that the lightning flashed back in the same path, as if there were an oscillating discharge. In another interesting flash, the path was not a crooked line but a wavy band, which was lit up four times in succession with equal brilliancy. The time between the second and third and the third and fourth flashes seemed longer than that between the first and second. The thunder which followed lasted about 80 seconds.

THE additions to the Zoological Society's Gardens during the past week include a Patas Monkey (*Cercopithecus patas* ♀) from West Africa, presented by Capt. T. W. Robinson; a Puma (*Felis concolor* ♂) from El Gran Chaco, presented by Mr. Alfred Grenfell, F.Z.S.; a Malayan Bear (*Ursus malayanus*) from Malacca, presented by Miss A. Stewart Saville; a —— Souslik (*Spermophilus* ——) from California, presented by Mr. B. F. Russell; a Gazelle (*Gazella dorcas* ♂) from Barbary, presented by Edward J. Hough; four Chukar Partridges (*Caccabis chukar*) from Persia, presented by Dr. J. Huntley; a —— Toad (*Bufo* ——) from Africa, presented by Mr. E. N. Wroughton; six Roseate Cockatoos (*Cacatua roseicapilla*), seventeen Cockateels (*Calopsitta novæ-hollandiæ*), six Swainson's Lorikeets (*Trichoglossus novæ-hollandiæ*), two Red-winged Parrakeets (*Aprosmictus erythropterus*), eight Chestnut-eared Finches (*Amadina castanotis*), two Peaceful Doves (*Geopelia tranquilla*) from Australia, a Nutmeg Bird (*Munia punctularia*), two Eastern Turtle Doves (*Turtur meena*) from India, three Magpie Tanagers (*Cissopis leveriana*), two Red-crested Cardinals (*Paroaria cucullata*), a Red Ground-Dove (*Geotrygon montana*), a Yarrell's Curassow (*Crax carunculata*), a Crested Curassow (*Crax alector*) from South-East Brazil, two Hawfinches (*Coccothraustes vulgaris*), British, deposited.

OUR ASTRONOMICAL COLUMN

THE MASS OF MERCURY.—In the *Bulletin Astronomique* for October Herr Backlund has published a new determination of the mass of Mercury deduced from the perturbations produced in the motion of Encke's comet arising from its close proximity to the planet in 1878. From the apparitions of the comet in 1871, 1875, 1878, 1881, and 1885, Herr Backlund finds the reciprocal of the mass of Mercury to be 2,668,700,—thus making the mass of the planet considerably larger than has been found by recent investigators. And Herr Backlund states that, even supposing the acceleration of the comet's mean motion to have been constant during the entire period 1871–85, it is not possible to represent satisfactorily the five apparitions of the comet during that period on the assumption that the reciprocal of the mass of Mercury is greater than 5,000,000.

THE NATAL OBSERVATORY.—Mr. Neison has issued his Report, as Superintendent of the Natal Observatory, for the year 1885. The staff of the Observatory consists of the Government Astronomer, an Astronomieal Assistant, and a Meteorological Assistant. Four ladies have also been employed during the year as astronomical computers. The equatorial appears to have been but little used in 1885, all the astronomical observations recorded having been made with the 3-inch transit. The total number of observations made with this instrument was 706, including transits of stars, of the sun, of the moon's limb, of the lunar crater Murchison A, and observations of zenith stars for latitude. With regard to the latter class of observations, it is proposed to determine the latitude of the Observatory with the greatest care, as one of the primary points of the geodetic triangulation of South Africa. Forty pairs of stars have been selected for this purpose, mostly differing in zenith distance by not more than 3′ or 4′. Also, with the view of better connecting the fundamental declinations of the star catalogues of northern and southern observatories, arrangements have been made for comparing, by Talcott's method, the zenith distances of a number of southern circumpolar stars with suitably placed northern stars of corresponding zenith distance. A list of thirty-two stars has been prepared for this purpose. Mr. Neison also reports on the state of his own work on the lunar theory, which he appears to consider of an official character.

COMET FINLAY (1886 *e*).—The following ephemeris of this object is by Dr. A. Krueger (*Astr. Nachr.*, No. 2755):—

For Berlin Midnight

1886	R.A. h. m. s.	Decl. ° ′	log *r*	log Δ	Brightness
Nov. 28	21 0 50	19 10·7 S.	9·9941	9·9142	3·0
30	21 10 58	18 20·4			
Dec. 2	21 21 12	17 27·2	9·9971	9·9060	3·1
4	21 31 30	16 31·0			
6	21 41 53	15 31·9	0·0016	9·8992	3·1
8	21 52 20	14 30·0			
10	22 2 49	13 25·6 S.	0·0074	9·8941	3·1

The brightness at date of discovery is taken as unity.

COMET BARNARD (1886 *f*).—The following ephemeris of this object for Berlin midnight is by Dr. Oppenheim (*Dun Echt Circular*, No. 130):—

1886	R.A. h. m. s.	Decl. ° ′	log *r*	log Δ	Brightness

The brightness at date of discovery is taken as unity.

GORE'S NOVA ORIONIS.—It seems to be clearly established that this interesting star is indeed—as was from the first suspected from the character of its spectrum—a simple variable, and not one of the class to which the title "temporary" can be fitly applied. M. Dunér, who had observed the star at intervals from last December to the end of April, found (*Astr. Nachr.*, No. 2755), on renewing his observations at the end of October and the beginning of the present month, that it had unmistakably increased in brightness in the interval, and was continuing to do so. Herr Fr. Schwab and Mr. Espin confirm this conclusion, the former having observed this star early in last July, and found it then fainter than the 12th magnitude. Its period would appear to be not far from one year; Herr Schwab gives it as one or two weeks longer than a year, and as ranging in brightness from 6m. to 12½m., whilst M. Dunér assigns a period of 359·5d. to it. It is clearly of importance that it should be carefully watched during the coming winter.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 NOVEMBER 28—DECEMBER 4

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on November 28

Sun rises, 7h. 42m.; souths, 11h. 48m. 10·4s.; sets, 15h. 55m.; decl. on meridian, 21° 21′ S.: Sidereal Time at Sunset, 20h. 25m.

Moon (three days after New) rises, 9h. 52m.; souths, 14h. 15m.; sets, 18h. 39m.; decl. on meridian, 19° 7′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	8 40	12 35	16 30	23 11 S.
Venus	7 33	11 43	15 53	20 51 S.
Mars	10 27	14 14	18 1	24 15 S.
Jupiter	3 55	9 12	14 29	9 14 S.
Saturn	19 5*	3 7	11 9	21 25 N.

* Indicates that the rising is that of the preceding evening.

Occultation of Star by the Moon (visible at Greenwich)

Dec.	Star	Mag.	Disap. h. m.	Reap. h. m.	Corresponding angles from vertex to right for inverted image ° °
3	h^1 Aquarii	$5\frac{1}{2}$	17 8	18 30	116 286

Dec.	h.	
3	5	Venus in superior conjunction with the Sun.
3	12	Mercury in inferior conjunction with the Sun.
4	4	Mercury at least distance from the Sun.

Variable Stars

M signifies maximum; *m* minimum.

Meteor Showers

The chief shower of the week is that of the *Taurids*; R A. 60°, Decl. 49° N. Other radiants active at this time are as follows:—Near η Persei, R.A. 44°, Decl. 56° N., slow, faint meteors; near α Canum Venaticorum, R.A. 194°, Decl. 43° N., very swift, streak-leaving meteors; from Leo Minor, R.A 155°, Decl. 36° N.; from near η Ursæ Majoris, R.A. 208°, Decl. 43° N. Fireball dates, November 29 and December 2.

TEN YEARS' PROGRESS IN ASTRONOMY[1]

II.

THE Solar Spectrum.—In 1877 Dr. Henry Draper, of New York, by a series of most laborious, time-consuming, and expensive researches, discovered the presence of oxygen in the sun, evidenced in his photographs, not by fine dark lines, as in the case of elements previously recognised, but by bright, hazy bands. It is difficult to assign any reason why this gas should behave so peculiarly and so differently from others, and for this reason many high authorities are indisposed to accept the discovery. But the evidence of the photographs seems fairly to outweigh any such purely negative theoretical objections.

Other advances have been made in the study of the spectrum, due mainly to the great improvements in spectroscopic apparatus. Until recently it has not been easy to decide with certainty as to some lines in the spectrum whether they were of solar or telluric origin; the great bands known as A and B, for instance. It was only in 1883 that the Russian, Egoroff, succeeded in proving that these are produced by the oxygen in the earth's atmosphere. In his experiments, on a scale previously unknown, the light was transmitted through tubes more than 60 feet in length, closed at the end with transparent plates, and filled with condensed gas.

It was quite early pointed out that the sun's rotation ought to produce a shift in the position of lines in the spectrum according as the light is derived from the advancing or receding edge of the solar disk, and Zollner thought he could perceive it. The earliest *measures*, however, were, I believe, those obtained independently by Vogel and the writer in 1876. In the great bisulphide of carbon spectroscope of Thollon the displacement becomes easy of observation; and very recently Cornu, by taking advantage of it, and by an extremely ingenious arrangement for making a small image of the sun to oscillate across the spectroscope slit two or three times a second, has been able to discriminate at a glance between the telluric and solar lines; the former stand firm and fast, while the latter seem to wave back and forth.

In this connection also should be mentioned the great map of the solar spectrum, for which Thollon received the Lalande Prize of the French Academy of Sciences last January, and the still more accurate and important map photographed by Prof. Rowland, by means of his wonderful diffraction-gratings, and now in course of publication. Nor would it be just either to omit the earlier and less accurate maps of Fievez and Vogel, which, when published, were as far in advance of anything before them as they are behind the new ones; nor the maps just made by Prof. Smyth, of Edinburgh.

It was in connection with the construction of such a map by Mr. Lockyer, that he was led to his theory of the compound nature of the so-called chemical elements, partly as a result of his comparisons of the spectra of different substances with the solar spectrum, and partly in consequence of considerations drawn from certain phenomena observed in the solar and stellar spectra themselves. His first paper on the subject was read late in 1878. This "working hypothesis," as its author calls it, has met with much discussion, favourable and unfavourable. It unquestionably removes many difficulties and explains many puzzling phenomena; at the same time there are very serious objections to it, and some of the arguments upon which Mr. Lockyer originally laid much stress have turned out unsound. For instance, he made a great point of the fact that, after all precautions are taken to remove impurities, several elementary substances show in their spectra common lines—"basic lines" he called them—indicating, as he thought, a common component. He found in the solar spectrum about seventy of these "basic lines." Now, under the high dispersion of our newer spectroscopes, these lines, which were single to his instruments, almost without exception dissolve into pairs and triplets, and withdraw their support from his theory.

I suppose that at present the weight of scientific opinion is against him; but, for one, I do not believe his battle is lost. In view of the law of Dulong and Petit, which establishes a relation between the atomic weight and specific heat of bodies, it seems to be pretty certain that *hydrogen* cannot be the elementary "*urstoff*" out of which all other elements are made by building up, as he at first seemed disposed to maintain; this element stands apparently on no different footing from the rest. But I see no reason why the elements, as we know them, may not constitute one *class* of bodies by themselves, all built up out of some as yet more elemental substance or substances. The "periodic law" of Mendelejeff suggests such a relation. And our received theories so stumble, hesitate, and falter in their account of many of the simplest phenomena of the solar and stellar atmospheres, that a strong presumption still remains in favour of the new hypothesis. I am not prepared to accept it yet; but certainly not to reject it.

The Chromosphere.—The study of the chromosphere and prominences has been kept up, very systematically and statistically, by Tacchini in Italy, and with less continuity, but still assiduously, by several other observers. I do not know, however, that any new results of much importance have been arrived at. The list of bright lines visible in their spectra has been a good deal enlarged; and Trouvelot thinks he has observed *dark* prominences—objective forms that show, black but active, upon the background of bright scarlet hydrogen in the surrounding chromospheric clouds. It may be that he is right; but, so far

[1] "Ten Years' Progress in Astronomy, 1876-86," by Prof. C. A. Young. Read May 17, 1886, before the New York Academy of Sciences. Continued from p. 69.

as I can learn, no other observer of the solar atmosphere has seen anything similar. I certainly have not myself. And I think some of his published observations of velocities of two or three thousand miles a second in the motions of the prominences, as evidenced by the displacement of lines in the spectrum, are still more questionable.

In two or three cases, prominences have been observed since 1876 considerably higher than any known previously. In October 1878 I myself observed one which attained an elevation of nearly 400,000 miles (13½′).

Eclipses and the Corona.—The sun's corona has been, perhaps, more earnestly studied than anything else about the central luminary, especially during the four eclipses which have occurred since 1876. At the eclipse of 1878, in the midst of an epoch of sunspot quiescence, the corona was found less brilliant than ordinary, and especially deficient in the unknown gas that produces the so-called 1474 line—the line which characterises the spectrum of the corona, and first demonstrated conclusively its solar origin in 1869. But while the corona at this time was less brilliant than it had been formerly, it was far more extensive. At least it seemed so; for, at Pike's Peak and Creston, Langley and Newcomb were able to follow its streamers to a distance of 6° from the sun. It is possible, however, that this extension was only due to the superior transparency of the mountain air.

The Egyptian eclipse of 1882 gave us some interesting results respecting the spectrum of the prominences and the corona. It appears that the light of the corona is especially rich in the ultra-violet, and in the photographs of the spectrum a number of bands are found which have been interpreted, with questionable correctness I think, as indicating the presence of carbon. The eclipse of 1883 was observed in the Pacific Ocean by French and American parties, but, I think, added very little real information. Prof. Hastings made an observation which he believed to establish a peculiar theory proposed by himself, viz. that the corona is merely a diffraction effect produced by the moon's limb, and depending on the non-continuity of phase in long stretches of light-vibrations. With a peculiar apparatus prepared expressly for the purpose, he found that at any moment the 1474 line was visible to a much greater distance from the sun on the side least deeply covered by the moon than on the other: as unquestionably would happen if his theory were correct. But the same thing would result from the mere diffusion of light by the air; and, notwithstanding his protests, the French observers who were at the same place, and nearly all others who have discussed the observations, think that this was the true explanation of what he saw. So far as I know, the discussion of the subject which has resulted from his publication has only strengthened the older view—that the corona is a true solar appendage; an intensely luminous but excessively attenuated cloud of mingled gas and fog and dust surrounding the sun, formed and shaped by solar forces.

The diffraction theory has one advantage—that it relieves us from stretching our conceptions as to the possible attenuation of matter to the extent necessary in order to account for the fact that a comet, itself mostly a mere airy nothing, experiences no perceptible retardation in passing through the coronal regions. There can be no question that this has happened several times: the last instance having been the great comet of 1882. But on careful consideration it will be found, I think, that our conceptions will bear the stretching without involving the least absurdity; a single molecule to the cubic foot would answer every necessary condition of the luminous phenomenon observed. And all the rifts and streamers, and all the radiating structure and curved details of form, cry out against the diffraction hypothesis.

The observations of the eclipse of 1885 (observed only by a few amateurs in New Zealand) have not proved important.

At present the most interesting debate upon the subject centres around the attempt of Mr. Huggins (first in 1883) to obtain photographs of the corona in full sunlight. He succeeded in getting a number of plates showing around the sun certain faint and elusive halo forms which certainly look very coronal. Plans were made and have been carried out, for using a similar apparatus on the Riffelberg, in Switzerland, and at the Cape of Good Hope. But so far nothing has been obtained much in advance of Mr. Huggins's own first results. Since September 1883, until very recently, the air has been full, as every one knows, of a fine haze, probably dust and vapour from Krakatão, which has greatly interfered with all such operations. It is now fast clearing away, and I for one am somewhat sanguine that a much greater success will be reached next winter at the Cape, and perhaps even in England during the coming summer.

Just about the same time that Huggins was photographing in England, Prof. Wright was experimenting in New Haven in a different way: isolating the blue and ultra-violet rays by the use of coloured media, stopping out the sun's disk, and receiving the image of the coronal regions on a fluorescent screen. He also had obtained what he believed, and still believes, to be a real image of the corona, when the aërial haze intervened to put an end to all such operations; for of course it is evident that whether one operates by this method or by photography, success is possible only under conditions of unusual atmospheric transparency and purity.

I suppose at present the predominant feeling among astronomers is that the case is hopeless, and that Huggins and Wright are mistaken. It may be so. But my own impression is that they are probably correct; although, of course, the matter is still in doubt.

Inferior Planets.—Leaving now the sun, and passing to the planetary system, we come first to the subject of intra-Mercurial planets.

The general opinion among astronomers (in which I fully concur) is that the question has been now fairly decided in the negative, *i.e.* it is practically certain that within the orbit of Mercury there is no planet of a diameter as large as five hundred miles, probably not one hundred. If such a one existed, it could not have failed to be discovered by the wide-angled photographs taken at the eclipses of 1882 and 1883, to say nothing of the visual observations. Of course, it is well known that at the eclipse of 1878 Prof. Watson supposed he had discovered two such bodies, and his extensive experience and his high authority led, for a time, to a pretty general acceptance of his conclusion. I notice that Dr. Ball, even very lately, in his "Story of the Heavens," is still disposed to credit the discovery. But Dr. Peters, by a masterly discussion of the circumstances of the observations themselves, and a comparison with the star maps, has shown that it is almost certain that Watson really saw only the two stars θ and ζ Cancri. In the same paper also, Peters examined all the observations of small, dark spots crossing the sun's disk which, up to that date (1879), had been made by Leverrier and others the ground for their belief in "Vulcan"; and he shows that they really afford no sufficient ground for the conclusion. As to Mr. Swift's supposed observation of two objects with large disks "both pointing to the sun," they certainly were not the two seen by Watson, while they were in the region covered by Watson and several other observers. What the precise nature of the mistake or illusion may have been it is perhaps not now possible to discover, but I think no one, unless perhaps Mr. Swift himself, now considers the observation important.

While, however, the question of a "Vulcan" is now pretty definitely settled, it is not at all impossible, or even improbable, that there may be intra-Mercurial asteroids, and that some of them may be picked up as little stars of the sixth magnitude or smaller, by the photographers at the eclipse of next August, or in 1887. The sensitiveness of our present photographic plate is now many times greater than it was even in 1882.

As to the planet Mercury, there is very little to report. It "transited" the sun in May 1878, and again in November 1881, and during the transits numerous measures were made of its diameter, giving results substantially in accord with the older values. I have already alluded, in connection with the earth's rotation, to Newcomb's investigation of former transits of this planet as establishing the sensible uniformity of the earth's rotation.

The planet Venus, by her transit in 1882, has attracted much attention, and much interest is felt as to the final outcome of the whole enormous mass of data, photographic and visual. Just how long we shall have to wait for the publication seems still uncertain. I have already said, however, that probably these transits will never again be considered as important as hitherto.

The most important physical observations upon the planet during the decade seem to be those of Langley, who, during the transit of 1882, observed a peculiar, and so far unexplained, illumination of one point on the edge of the planet's disk, and those of Trouvelot and Denning, who have observed and figured certain surface-markings of the planet. I think I may fairly mention also our Princeton observation of the spectrum of the planet's atmosphere during the transit, and our confirmation of Gruithuisen's old observation of a white cap (likely enough an ice-cap), at the edge of the planet's disk—probably marking the planet's pole, and showing that the planet's equator has no such anomalous inclination of 50° or 60°, as stated in some of the current text-books. This cap has also been observed by Trouvelot and Denning. But this lovely planet is most refractory and unsatisfactory as a telescopic object, apparently enveloped in dense clouds which mostly hide the real surface of the globe, and mock us with a meaningless glare.

We mention in passing, but without indorsement, the speculations of Houzeau, who has attempted to account for some of the older observations of a satellite to Venus, by supposing another smaller sister planet, "Neith," circling around the sun in an orbit a little larger than that of Venus, and from time to time coming into conjunction with it. But the theory is certainly untenable; a planet large enough to show phases, as the hypothetical satellite is said to have done, in the feeble telescopes with which many of the observations were made 100 years ago or more, would be easily visible to the *naked eye even*. There can be little doubt that all the Venus satellites so far observed are simply *ghosts* due to reflections between the lenses of the telescope, or between the cornea of the eye and the eye lens.

Mars.—But while Venus has gained no moons during the past ten years, Mars has acquired two, and they are both native Americans. There is no need to recount the faithful work of Prof. Hall with the then new great telescope at Washington, and its brilliant result; brilliant in a scientific sense, that is, for, regarded as luminaries, it must be admitted that the Martial satellites, in spite of their formidable names of Phobos and Deimos, do not amount to much. Under the best of circumstances, they are too faint to be seen by any but keen eyes at the end of great telescopes. Small as they are, however, the little creatures punctually pursue the orbits which Hall has computed for them, and, when the planet came to its opposition a few weeks ago, they were found just in their predicted places. They are interesting, too, from the light they throw upon the genesis and evolution of the planetary system, almost compelling the belief that they have come *gradually* into their present relation to the planet. The inner one, Phobos, revolves around the primary in 7h. 39m., which is less than one-third of the planet's day. The theory of "tidal evolution," proposed by Prof. G. H. Darwin in 1878-80, as the result of his investigations upon the necessary mechanical consequence of the tidal reactions between the earth, sun, and moon, will account for Phobos, and I know nothing else that will; though, of course, it would be rash to assert that no other account can ever be given.

Much attention has also been paid to the study of the planet's surface. In 1876 we were already in possession of three elaborate maps, by Proctor, Kaiser, and Terby, agreeing in the main as to all the characteristic formations. In 1877, Schiaparelli, of Milan, detected, or thought he did, on the planet's surface, a numerous system of "canals"—long, straight channels, some of them more than 1000 miles in length, with a pretty uniform width of fifty or sixty miles; and from his observations he constructed a new map, differing from the older ones somewhat seriously, though still accordant in the most essential features. His nomenclature of the seas and continents, derived from ancient geography, is certainly a great improvement on that of his predecessors, who had affixed to them the names of their friends and acquaintances among living astronomers. There has been some scepticism as to the reality of these "canals"; but in 1879 and 1881 they were all recovered by Schiaparelli, and several other observers, notably Burton, also made them out. Moreover, Terby finds, from drawings in his possession, that they had before been seen, though not understood or clearly recognised, by Dawes, Secchi, and other observers. At present the balance of evidence is certainly in their favour, especially as the observers at Nice report seeing them last spring. I do not think the same can be said in respect to another observation of Schiaparelli's on the same object, made in 1881. He then found nearly all of these canals—more than twenty of them—to be *double*, *i.e.* in place of a single canal there were two—parallel, and 200 or 300 miles apart. No one else so far has confirmed this "gemination" of the canals; but the planet does not come to a really favourable opposition again until 1890 and 1892, when probably the question can be settled.

The time of rotation has during the past year been determined with great accuracy by Bakhuyzen, who has corrected some errors of Kaiser and Proctor, and finds it 24h. 37m. 22·66s. In 1876 there still remained some question as to the amount by which the planet is flattened at the poles. The majority of observers had found a difference between equatorial and polar diameters amounting to between 1/100 and 1/30, while, on the other hand, a few of the best observers had found it insensible. The writer, in 1879, made a very careful determination, and found it 1/219, a quantity closely agreeing with the theoretical value deduced by Adams as probable from the motion of the newly-discovered satellites.

The Asteroids.—On May 1, 1876, the number of known asteroids was 163. To-day it stands at 258, 95 of these little bodies having been discovered within the decade, 45 of them by one man, Palisa, of Vienna, while our own Peters is responsible for 20.

None of the new ones are especially remarkable, *i.e.* some of the older ones are always more so; the most inclined and most eccentric orbits, the longest and the shortest periods, none of them belong to any of the late discoveries. One point is noteworthy, that the more recently discovered bodies are much smaller than the earlier ones. The first 25, discovered between May 1876 and October 1878, have an average opposition magnitude of 11·2, while the last 25, discovered since April 1883, average only 12·2; *i.e.* the first 25 average about $2\frac{1}{2}$ times as bright as the last. Out of the whole 95, two are of the 9th magnitude (one of them, No. 234, was discovered as recently as August 1883), 14 are of the 10th, 33 of the 11th, 33 of the 12th, and 13 of the 13th. Of these last 13, 10 have been found within the past two years; and of the 12 others found in the same time, 6 are of the 11th magnitude, and 6 of the 12th.

It is clear that there can remain very few to be discovered as large as the 10th magnitude, but there may be an indefinite number of the smaller sizes.

The Major Planets.—As regards the planet Jupiter, the one interesting feature for the past ten years has been "the great red spot." This is an oval spot, some 30,000 miles in length, by 6000 or 7000 in width, which first attracted attention in 1878. At first, and for three years, it was very conspicuous, but in 1882 it became rather faint, though still remaining otherwise pretty much unchanged. In 1885 it was partly covered with a central whitish cloud, which threatened to obscure it entirely; but this season the veiling cloud has diminished, and the marking is again as plain as it was in 1882 or 1883. How long it will continue, no one can say; nor is there any general and authoritative agreement among astronomers as to its nature and cause.

In connection with observations upon this object, several new determinations have been made of the planet's rotation-period, and they all show that, as in the case of the sun, the equatorial markings complete the circuit more rapidly than in higher latitudes; a white spot near the equator gives 9h. 50m. 6s., as against 9h. 55m. 36s. for the red spot, which is approximately in latitude 30°.

We must not omit to mention Prof. Pickering's new photometric method of observing the eclipses of this planet's satellites. Instead of contenting himself with observing merely the moments of their disappearance and reappearance—an observation not susceptible of much accuracy—he makes a series of rapid comparisons between the brightness of the waning or waxing point of light during the two or three minutes of its change, using, as the standard, one of the neighbouring uneclipsed satellites. From these comparisons he determines the moment when the satellite under eclipse has just half its normal brightness, and this with a probable error hardly exceeding a single second, while the old-fashioned method gave results doubtful by not less than a quarter of a minute. Cornu and Obrecht have independently introduced the same method at Paris. When we have a complete twelve years' series of such observations, they will give an exceedingly precise determination of the time required by light to traverse the earth's orbit, and so, indirectly, of the solar parallax.

As regards Saturn, there is nothing to report so startling as Jupiter's red spot. A white spot, which appeared in 1877, enabled Hall to make a new determination of the rotation-period, which came out 10h. 14m. 14s. This is in substantial accord with an earlier determination of W. Herschel's (10h. 16m. 7s.), but involves a serious correction of the value 10h. 29m. 17s. given in most of the text-books. The error probably came from a servile copying of a slip of the pen made by some book-compiler, fifty years ago or more, in accidentally writing Herschel's value of the rotation of the inner ring, instead of that of the planet.

Much time has been spent in observations of the rings, and Trouvelot has reported a number of remarkable phenomena, most of which, however, he alone has seen as yet. The most recent micrometric measures have failed to confirm Struve's suspicion that the rings are contracting on the planet. Extensive series of observations have been made upon the satellites by H. Struve, Meyer, and others in Europe, and by Hall in this country. Hall's observations are especially valuable, and the series is now so nearly completed that we may soon hope to have most accurate tables. In the case of Hyperion, there is found a singular instance of a *retrograde* motion of the line of apsides of the orbit, produced by the action of an *outside* body, the effect being due to the near commensurability of the periods of Hyperion and Titan. This most peculiar and paradoxical disturbance first showed itself as an observed fact in Hall's observations; and, soon after, Newcomb gave the mathematical explanation and development. He finds the mass of Titan to be about 1/12,500 that of Saturn. It may be noted, too, that Hall's observations of the motions of Mimas and Enceladus indicate for the rings a mass less than 1/10 that deduced by Bessel: instead of being 1/100 as large as the planet, they cannot be more than 1/1000, and are probably less than 1/10,000.

The satellites of Uranus have also been assiduously observed at Washington, so that at present the Uranian system is probably as accurately determined as the Jovian, perhaps more so. The form of the planet has been shown to be decidedly elliptical (about 1/14) by observations of Schiaparelli and at Princeton; and the same observers have detected faint belts upon the disk, which have also been seen at Nice, and by the Henrys in Paris. Many of the observations appear to indicate a very paradoxical fact—that the belts, and consequently the planet's equator, are inclined to the orbits of the satellites at a considerable angle. The mathematical investigations of Tisserand appear to demonstrate that, in the case of a planet perceptibly flattened at the poles, satellites near enough to be free from much solar disturbance must revolve nearly in the plane of the equator; while those more remote, and disturbed more by the sun than by the protuberant equator of the planet, must revolve nearly in the plane of the planet's orbit. Thus the two satellites of Mars, the four satellites of Jupiter, and the seven inner satellites of Saturn, all move nearly in the equatorial plane, while our moon and Japetus move in ecliptical orbits. It is very difficult to believe that the satellites of Uranus, which are certainly not ecliptical and are very near the planet, do not move equatorially. And yet it is unquestionable that most of the observations with sufficiently powerful telescopes (my own among them) do seem to indicate pretty decidedly that the planet's equator is inclined as much as 15° or 20° to the orbit plane of the satellites.

As to Neptune, there is nothing new. One or two old observations of the planet have turned up in the revision of old star catalogues, and Hall, of Washington, has made a careful and accurate determination of the orbit of its one satellite, and of the planet's mass; while Maxwell Hall, of Jamaica, has deduced a very doubtful value of the planet's rotation from certain photometric observations of its brightness.

There has been some hope that a planet beyond Neptune might be found. Guided by certain slight indications of systematic disturbances in the motion of Neptune, Todd made an extended search for it in 1877-78, using the Washington telescope, and hoping to detect it by its disk, but without results. If such a planet exists, it is likely to appear as a star between the 11th and 13th magnitude, and may be picked up any time by the asteroid-hunters. But its slow motion, and the fact that our present charts give but few stars below the $11\frac{1}{2}$ magnitude, will render the recognition difficult.

The indications I have spoken of, and certain others first noted in 1880 by Prof. G. Forbes, and depending upon the behaviour of certain periodic comets, furnish pretty strong reasons for believing in its existence, though as yet they fall far short of making it certain.

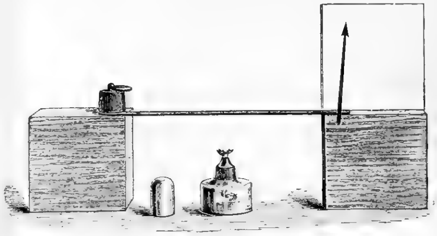
(*To be continued.*)

A LECTURE EXPERIMENT ON THE EXPANSION OF SOLIDS BY HEAT

I VENTURE to call attention to a simple and effective way of demonstrating the linear expansion of solids when heated, first suggested, I believe, by M. Kapoustine (*Journal de Physique*, December 1883, p. 576). It answers at least as well as the system of levers known as "Ferguson's pyrometer," which is usually employed for the purpose, while the cost of the apparatus is almost nothing, and any one can make it in ten minutes.

The principle is, to magnify the slight extension of a bar by causing the end of it to roll upon a needle, and thus turn the latter round and move a pointer attached to it through a sensible arc.

The figure given below will show the nature of the apparatus.



A small flat rod of the material to be examined, such as brass, iron, or glass, about 30 cm. long, 1 cm. broad, and 2 or 3 mm. thick, is laid upon two wooden blocks, placed about 25 cm. apart. A weight is put upon one end of the rod to keep it from moving; under the other end, at right angles to the length of the rod, is laid a fine sewing-needle, to the eye-end of which a light pointer of straw, about 16 or 20 cm. long, is attached by sealing-wax. Behind the pointer (which is painted black) a screen of white cardboard is fixed on the wooden block by drawing-pins.

When the rod is heated by a lamp-flame, the free end of it, as it expands, moves forward upon the needle and rolls it round, its movement being shown by the motion of the pointer. Even the slight expansion of a slip of glass is thus easily rendered evident to a class.

I have constructed for my own use a double apparatus on the same principle, in which the surfaces between which the needle rolls are of brass, ground true and flat. Two bars of different materials lie side by side, each having its own bit of needle and aluminium pointer, ranging over the same scale. They are heated equally by a broad flame (spirits of wine in a wide trough) and the difference of expansibility as well as the fact of expansion by heat is thus shown.

It is advisable to counterpoise the pointer by putting a shot or two into the lower end of the straw which projects below the needle, and cementing them in by sealing-wax. Also, before the experiment is shown to an audience, it is well to make sure that the needle rolls fairly and freely between the bar and the block. Such precautions, however, are not in the slightest degree necessary for school-work; for there is always one thing which gives the typical boy greater pleasure than to see an experiment succeed, and that is—to see it fail.

Eton College H. G. MADAN

COMPARATIVE STUDIES UPON THE GLACIATION OF NORTH AMERICA, GREAT BRITAIN, AND IRELAND[1]

OBSERVATIONS extending over several years upon glacial phenomena on both sides of the Atlantic had convinced the author of the essential identity of these phenomena; and the object of this paper was to show that the glacial deposits of Great Britain and Ireland, like those of America, may be interpreted most satisfactorily by considering them with reference to a series of great *terminal moraines*, which both define confluent

[1] Abstract of a Paper read at the Birmingham meeting of the British Association, September 1886, by Prof. H. Carvill Lewis, M.A., F.G.S.

lobes of ice and also often mark the line separating the glaciated from the non-glaciated areas.

The paper began with a sketch of recent investigations upon the glaciation of North America, with special reference to the significance of the terminal moraines discovered within the last few years. The principal characters of these moraines were given, and a map was exhibited showing the extent of the glaciated areas of North America, the course of the interlobate and terminal moraines, and the direction of striation and glacial movement. It was shown that, apart from the great ice sheet of North-Eastern America, an immense lobe of ice descended from Alaska to Vancouver's Island on the western side of the Rocky Mountains, and that from various separate centres in the Cascade, Sierra Nevada, and Rocky Mountains there radiated smaller local glaciers.

The mountains encircling the depression of Hudson Bay seemed to be the principal source of the glaciers which became confluent to form the great ice-sheet. In its advance, this ice-sheet probably met and amalgamated with a number of already existing local glacial systems, and it was suggested that there was no necessity for assuming either an extraordinary thickness of ice at the Pole, or great and unequal elevations and depressions of land.

Detailed studies made by the author in Ireland in 1885 had shown remarkably similar glacial phenomena.

The large ice-sheet which covered the greater part of Ireland was composed of confluent glaciers, while distinct and local glacial systems occurred in the non-glaciated area. The principal ice-sheet resembled that of America in having for its centre a great inland depression surrounded by a rim of mountains.

These appear to have given rise to the first glaciers, which, after uniting, poured outwards in all directions. Great lobes of this ice-sheet flowed westward out of the Shannon and out of Galway, Clew, Sligo, and Donegal Bays, northward out of Loughs Swilly and Foyle, and south-eastward out of Dundalk and Dublin Bays; while to the south the ice-sheet abutted against the Mullaghareirk, Galty, and Wicklow Mountains, or died out in the plains.

Whether it stopped among the mountains or in the lowlands, its edge was approximately outlined by unusual accumulations of drift and boulders, representing the terminal moraines. As in America, this outer moraine was least distinct in the lowlands, and was often bordered by an outer "fringe" of drift several miles in width.

South of an east and west line extending from Tralee to Dungarvan is a non-glaciated zone free from drift. Several local systems of glaciers occur in the South of Ireland, of which by far the most important is that radiating from the Killarney Mountains, covering an area of 2000 square miles, and entitled to be called a local ice-sheet. Great glaciers from this Killarney ice-sheet flowed out of the fjord-like parallel bays which indent the south-western coast of Ireland. At the same time the Dingle Mountains, the Knockmealdown and Comeragh Mountains, and those of Wexford and Wicklow furnished small separate glaciers, each sharply defined by its own moraine.

No evidence of any great marine submergence was discovered, although the author had explored the greater part of Ireland, and the eskers were held to be phenomena due to the melting of the ice and the circulation of sub-glacial waters. The Irish ice-sheet seemed to have been joined at its north-eastern corner by ice coming from Scotland across the North Channel. All the evidence collected indicates that a mass of Scotch ice, reinforced by that of Ireland and England, filled the Irish Sea, over-riding the Isle of Man and Anglesey, and extending at least as far south as Bray Head, south of Dublin. A map of the glaciation of Ireland was exhibited in which the observations of the Irish geologists and of the author were combined, and in which was shown the central sheet, the five local glacial systems, all the known striæ, and the probable lines of movement as indicated by moraines, striæ, and the transport of erratics.

The glaciation of Wales was then considered. Wales was shown to have supported three distinct and disconnected local systems of glaciers, while at the same time its extreme northern border was touched by the great ice-lobe filling the Irish Sea. The most extensive local glaciers were those radiating from the Snowdon and Arenig region, while another set of glaciers radiated from the Plinlimmon district and the mountains of Cardiganshire, and a third system originated among the Brecknockshire Beacons. The glaciers from each of these centres transported purely local boulders and formed well-defined terminal moraines. The northern ice-lobe, bearing granite boulders from Scotland and shells and flints from the bed of the Irish Sea, invaded the northern coast, but did not mingle with the Welsh glaciers. It smothered Anglesey and part of Carnarvonshire on the one side and part of Flintshire on the other, and heaped up a terminal moraine on the outer flanks of the North Welsh mountains. This great moraine, filled with far-travelled northern erratics, is heaped up in hummocks and irregular ridges, and is in many places as characteristically developed as anywhere in America. It has none of the characters of a sea-beach, although often containing broken shells brought from the Irish Sea. It may be followed from the extreme end of the Lleyn Peninsula (where it is full of Scotch granite erratics), in a north-easterly direction through Carnarvonshire past Moel Tryfan and along the foot of the mountains east of Menai Strait to Bangor, where it goes out to sea, re-appearing further east at Conway and Colwyn. It turns south-eastward in Denbighshire, going past St. Asaph and Halkin Mountain. In Flintshire it turns southward, and is magnificently developed on the ea tern side of the mountains, at an elevation of over 1000 feet, between Minera and Llangollen, south-west of which place it enters England. There is evidence that, where the ice-sheet abutted against Wales, it was about 1350 feet in thickness. This is analogous to the thickness of the ice-sheet in Pennsylvania, where the author had previously shown that it was about 1000 feet thick at its extreme edge, and 2000 feet thick at points some 8 miles back from its edge. The transport of erratics coincides with the direction of striæ in Wales as elsewhere, and is at right angles to the terminal moraine.

The complicated phenomena of the glaciation of England, the subject of a voluminous literature and discordant views, had been of high interest to the author, and had led him to redouble his efforts for its solution. He had found that it was possible to accurately map the glaciated areas, to separate the deposits made by land ice from those due to icebergs or to torrential rivers, and to trace out a series of terminal moraines both at the edge of the ice-sheet and at the edge of its confluent lobes. Perhaps the finest exhibition of a terminal moraine in England is in the vicinity of Ellesmere, in Shropshire. A great mass of drift several miles in width, and full of erratics from Scotland and from Wales, is here heaped up into conical hills which inclose "kettle holes" and lakes, and have all the characters of the "kettle-moraine" of Wisconsin. Like the latter, the Ellesmere moraine here divides two great lobes of ice, one coming from Scotland, the other from Wales. This moraine may be traced continuously from Ellesmere eastward through Madeley, Macclesfield, to and along the western flank of the Pennine Chain, marking throughout the southern edge of the ice-sheet of northern England. From Macclesfield the same moraine was traced northward past Stockport and Staleybridge to Burnley, and thence to Skipton in Yorkshire. North-east of Burnley it is banked against the Boulsworth Hills up to a height of 1300 feet in the form of mounds and hummocks. South and east of this long moraine no signs of glaciation were discovered, while north and west of it there is every evidence of a continuous ice-sheet covering land and sea alike. The striæ and the transport of boulders agree in proving a southerly and south-easterly direction of ice-movement in Lancashire and Cheshire.

From Skipton northward the phenomena are more complicated. A tongue of ice surmounted the watershed near Skipton, and protruded down the valley of the Aire as far as Bingley, where its terminal moraine is thrown across the valley like a great dam, reminding one of similar moraine dams in several Pennsylvania valleys. A continuous moraine was traced around this Aire glacier. Another great glacier, much larger than this, descended Wensleydale and reached the plain of York. The most complex glacial movements in England occurred in the mountain region about the Nine Standards, where local glaciers met and were overpowered by the greater ice-sheet coming down from Cumberland. The ice-sheet itself was here divided, one portion going southward, the other in company with local glaciers and laden with the well-known boulders of "Shap granite" being forced eastward across Stainmoor Forest into Durham and Yorkshire, finally reaching the North Sea at the mouth of the Tees. The terminal moraine runs eastward through Kirkby Ravensworth, toward Whitby, keeping north of the Cleveland Hills, and all Eastern England south of Holderness appears to be non-glaciated. On the other hand, all England north of Stainmoor Forest and the River Tees, except the very highest points, was smothered in a sea of solid ice.

There is abundant evidence to prove that the ice-lobe filling the Irish Sea was thicker towards its axis than at its edges, and at the north than at its southern terminus, and that it was reinforced by smaller tributary ice-streams from both England and Ireland. It may be compared with the glacier of the Hudson River Valley in New York, each having a maximum thickness of something more than 3000 feet. The erosive power of the ice-sheet was found to be extremely slight at its edge, but more powerful farther north, where its action was continued for a longer period. Towards its edge its function was to fill up inequalities rather than to level them down. It was held that most glacial lakes are due to an irregular dumping of drift, rather than to any scooping action, observations in England and in Switzerland coinciding with those in America to confirm this conclusion. Numerous facts on both sides of the Atlantic indicate that the upper portion of the ice-sheet may move in a different direction from its lower portion. It was also shown that a glacier in its advance had the power of raising stones from the bottom to the top of the ice, a fact due to retardation by friction of its lower layers. The author had observed the gradual upward passage of sand and stones in the Grindelwald glacier, and applied the same explanation to the broken shells and flints raised from the bed of the Irish Sea to the top of Moel Tryfan, to Macclesfield, and to the Dublin mountains.

The occurrence of stratified deposits connected with undoubted moraines, was shown to be a common phenomenon, and instances of stratified moraines in Switzerland, Italy, America, and Wales, were given. The stratification is due to waters derived from the melting ice, and is not proof of submergence.

It was held that, notwithstanding a general opinion to the contrary, there is no evidence in Great Britain of any marine submergence greater than about 450 feet. It was to be expected that an ice-sheet advancing across a sea-bottom should deposit shell-fragments in its terminal moraine. The broad principle was enunciated that wherever in Great Britain marine shells occur in glacial deposits at high levels, it can be proved both by striæ and the transport of erratics that the ice advanced on to the land from out of the sea. The shells on Three Rock Mountain near Dublin, and in North Wales and Macclesfield, all from the Irish Sea; the shells in Cumberland transported from Solway Firth; those on the coast of Northumberland brought out of the North Sea; those at Airdrie in Scotland, carried eastward from the bottom of the Clyde; and those in Caithness from Moray Firth, were among examples adduced in proof of this principle. The improbability of a great submergence not leaving corresponding deposits in other parts of England was dwelt upon.

It was also held that there was insufficient evidence of more than one advance in the ice-sheet, although halts occurred in its retreat. The idea of successive elevations and submergences with advances and retreats of the ice was disputed, and the author held that much of the supposed inter-glacial drift was due to sub-glacial waters from the melting ice.

The last portion of the paper discussed the distribution of boulders, gravels, and clays south of the glacial area. Much the greater part of England was believed to have been uncovered by land ice. The drift deposits in this area were shown to be the result in part of great fresh-water streams issuing from the melting ice-sheet and in part of marine currents bearing icebergs during a submergence of some 450 feet. The supposed glacial drift about Birmingham and the concentration of boulders at Wolverhampton were regarded as due to the former agent, while the deposits at Cromer and the distribution of Lincolnshire chalk across Southern England were due to the latter. The supposed esker at Hunstanton was held to be simply a sea-beach, and the London drift deposits to be of aqueous origin. Thus the rival theories of floating icebergs and of land glaciers were both true, the one for Middle and Southern England, the other for Scotland, Wales, and the North of England; and the line of demarkation was fixed by great terminal moraines. The paper closed with an acknowledgment of indebtedness to the many geologists in England and Ireland who had uniformly rendered generous assistance during the above investigation.

THE CLIMATE OF NORTHERN EUROPE AND THE GULF STREAM

IN view of the reference made by Sir William Dawson, in his inaugural address at the meeting of the British Association, to the effect of the Gulf Stream on the climate of Northern Europe, particularly that of Norway, and the consequences of a diversion of the stream from its present course, the following contribution to the subject by the well-known Norwegian *savant*, Dr. Karl Hesselberg, which appeared in a recent number of the scientific journal *Naturen*, may be of interest and tend to its further elucidation.

According to the situation of Norway on the globe, the northern part of the country should have a distinct Polar climate, with eternal ice and snow, a home only for the Eskimo and Polar bears. Several circumstances contribute, however, to make it otherwise. The country forms a western promontory of the great Asiatic-European continent, and receives its full share of the advantages of such a situation. Mild south-west winds blow throughout the year, while warm sea-currents wash its extensive shores summer as well as winter. The winter cold is so reduced that only a small portion of the heat of the summer sun is consumed in melting the snow. The length of the summer days, too, which north of the Polar Circle last twenty-four hours, contribute to raise the mean temperature, and accelerate the growth of the flora. Certain other circumstances, as, for instance, the formation of the country and the physico-geographical conditions of the North Atlantic Ocean, contribute equally to make the Norwegian climate one of the most favourable in the world. A brief *résumé* of the circumstances will be of interest.

A chart of the distribution of the atmospheric depression in the North Atlantic Ocean—the Norwegian Sea—shows that all the year round a strong barometric minimum prevails in the middle of the sea between Norway, Iceland, Jan Mayen, and Spitzbergen, the consequence of which is that south-west winds always blow in the eastern part of this area, viz. along the coast of Norway. Warm water is thereby forced up towards Norway and Spitzbergen, even into the East Arctic Ocean. The bottom formation of the sea, too, contributes to preserve the high temperature. If a chart be examined of the depths of the North Atlantic Ocean, such a one, for instance, as is the result of Prof. Mohn's labours after the measurements of the Norwegian North Atlantic Expedition, it will be found that the sea-bottom between Norway, the Faroe Islands, Iceland, and Jan Mayen, forms a basin with a depth of a little over 2000 English fathoms. It will also be seen that the Norwegian coast does not fall abruptly into this abyss, but that the bottom along the whole coast slopes gradually down from the shore seawards to a certain point where it terminates perpendicularly. In other words, Norway is surrounded with a continuous "bank," which in a great measure contributes to preserve the high temperature along the coast. In the great basin, however, the water is icy cold at the bottom, but against this the bank forms a natural barrier, whilst above the bank the warm water is without any bottom layer of cold. It is the warm water which fills the fjords and there preserves a temperature so high that it is sometimes higher than the mean temperature of the air, and under which the fjords do not freeze, a circumstance of great importance. If the temperature of the sea-water in the winter contributes to raise the temperature of the air, it will in the summer have the opposite effect, and cause the climate to be very much tempered along the coast. It is only in the fjords and adjacent valleys that the temperature in the summer rises to a height unusual for the latitude.

In order to show the relatively favourable climate which Norway enjoys, Dr. Hesselberg supplies two diagrams. The first of these shows the mean temperature of the air over Europe and the North Atlantic Ocean in January, when it is lowest. Isotherms are shown for every fifth degree. If now, for instance, the isotherm 0°—the temperature of the air—be followed, it will at once be seen how far it shoots up northwards between Iceland and Norway, in fact, right above lat. 70° N. In tead of running east and west, it goes nearly straight north and south, particularly along the west coast of Norway, which it follows throughout its entire length, from the latitude of Tromsö to that of Christiansand. Hence it deviates towards Denmark, then runs into the Baltic, returns to Hamburg, and thence runs in a south-easterly direction across Europe, nearly down to the Adriatic Sea. Here it first trends eastwards, across Turkey and the Black Sea. Off the Norwegian coast, therefore, in lat. 70° N., the same mean temperature prevails in January as in Southern Europe in lat. 45°, and even there the mean temperature is probably 3° higher than might be expected according to the latitude. The other isotherms have a similar course, as well as the temperature at the surface of the sea. A great wave of warm water rolls up along the coast of Norway, and may be traced even to Spitzbergen.

Another equally interesting illustration of the mildness of the winter in Norway is shown by two diagrams of the "thermal anomaly" in January. By way of comparison the month of July is included. It may be added that by thermal anomaly is meant the difference which exists between the *true* mean temperature of a place and the mean temperature *actually registered* in that latitude.

In January the thermal anomaly is very remarkable. Thus, along the coast of Norway, between the northernmost and westernmost promontories, the North Cape and Stat, it reaches + 20° C., and in the sea outside most probably + 25° C. These figures are certainly very remarkable. Eastwards, it decreases inland, but even here—where the cold is very great in the winter—it never falls below + 7°. In the Baltic, on the other hand, it again rises, as might be expected.

In the summer, however, the conditions are far from being so favourable. There is, indeed, then a narrow strip of land, on the very verge of the coast, where the thermal anomaly is slightly *negative*. The line for the 0° C. anomaly then follows the west coast, decreasing gradually seawards, whilst eastwards, across Southern Norway, it rises to + 4° C., and in Finmarken to + 70° C.

For the further elucidation of this, the following comparison of the January mean temperature in various places on the globe in about the same latitude may serve :—

About 60° *N. lat.*	°
Hellisö Lighthouse	2
Bergen	0
Christiania	− 5
Stockholm	− 3
St. Petersburg	− 10
Jakutsk	− 42
North Kamchatka	− 20
South Alaska	− 20
Great Slave Lake	− 25
North Coast of Labrador	− 25
Cape Farewell	− 7
Shetland Islands	4

About 71° *N. lat.*	°
North Cape	− 4
South Novaya Zemlya	− 20
Mouth of the Yenisei	− 34
Mouth of the Lena	− 40
Point Barrow	− 30
Boothia	− 32
Upernivik	− 20
Jan Mayen	− 10

The coldest place on the globe where the mean temperature has been *exactly* ascertained, viz. Werchojansk, in the interior of Siberia, with − 48° C. in January, lies in the same latitude as Bodö, where it is − 2° C., and Röst, with 0°·5 C.

In order to obtain correct normal values of the temperature in a place, long and continuous series of observations are necessary; and when we consider that the longest we possess for any place only extends over 100 years, and that meteorology is but a science of yesterday, the Norwegian meteorological records can make a fair show. With regard, however, to the changes which take place in the climate in a certain spot during ages—which occurrence is beyond dispute—we have no reliable data. I will only mention here Prof. Blytt's theory,[1] which has attracted many supporters, viz. that the periodical changes in the climate are due to the precession of the equinoxes (with a mean period of about 21,000 years), and to changes in the eccentricity of the earth's orbit.

It is, however, possible to accept a shorter periodical change in the climate than this, and theories on this point have not been wanting; but the only one which has found any support is the eleven-year period, corresponding to that of the sunspots, which again coincides with that of the terrestrial magnetic phenomena. It has even been attempted to bring the fall of rain and snow within a certain law, and, as some maintain, with success; but in my opinion the proofs advanced in support of such a theory are far from being conclusive.

TO PROVE THAT ONLY ONE PARALLEL CAN BE DRAWN FROM A GIVEN POINT TO A GIVEN STRAIGHT LINE

(1) LET OP and OQ be two lines at right angles, and let PQ move along them from O, so that OP always = OQ. Then PQ always > OQ or OP.

Hence if OQ increase without limit, PQ must also do so.

Let ON bisect the angle POQ. Then N bisects PQ.

Then if OQ increase without limit, QN does so (QN = ½ QP).

If OQ′ be taken along ON = OQ, QQ′ > QN.

Hence if OQ increase without limit, QQ′ does so.

Similarly by bisecting Q′OQ by OM, we can show that QM increases without limit with OQ, and so on by continual bisection. Hence—

If two straight lines meet at any angle, the perpendicular from a point of one on the other becomes infinite when that point is at infinity.

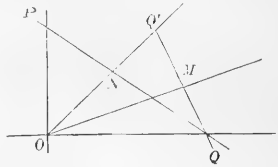

FIG. 1.

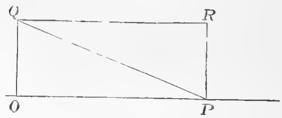

FIG. 2.

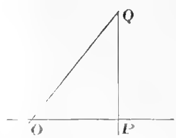

FIG. 3.

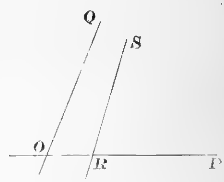

FIG. 4.

(2) Let OQ be some given length taken at right angles to a line OP;

Let PR move along OP at right angles to OP, so that PR always = OQ.

Join QR, QP.

Let OP increase without limit.

Then the angle PQR tends to become zero.

For the lines QR, PQ never become infinitely separated.

Thus there is evidently some definite position for the line QP when OP becomes ∞.

(3) Let a line PQ move at right angles to OP, so that PQ = OP.

Then if OP increase without limit, OQ increases without limit.

Hence, there is some finite angle, QOP, such that the perpendicular QP from Q at ∞ on OP falls at an infinite distance from O.

The same thing is evidently true for all angles less than QOP.

Then either it is true of all angles less than a right angle, in which case it can be easily shown that only one parallel can be drawn from a given point to a given line;

Or, there is some limiting angle, QOP, for which QP falls at ∞, and for any greater angle (< right angle) QP falls at some finite distance from O.

Let Q O P be this limiting angle. Take R on O P, and draw R S to Q at ∞ along O Q.

Then if S is at ∞, the perpendicular S P falls at an infinite distance from R.

∴ Angle P R S not greater than P O Q, and it cannot be less (Eucl., I., 16 and 27).

Hence it must be equal.

Hence R S making the angle S R P = Q O P meets O Q at ∞ at both ends.

And any other straight line through R becoming infinitely distant from R S must cut O Q in some finite point.

Thus from R only one parallel, R S, can be drawn to a given line, O Q.

By moving O P along O Q always at the same angle, Q O P, we can show that

From a given point only one parallel can be drawn to a given line.

This theorem, therefore, must be true. E. BUDDEN

SCIENTIFIC SERIALS

American Journal of Science, October.—A dissected volcanic mountain; some of its revelations, by James D. Dana. Here the author returns to the subject of Tahiti, largest of the Society Islands, already described by him in 1850 from materials supplied by the Wilkes Exploring Expedition of 1839. The old cone, some 7000 feet high, is now a dissected mountain, with valleys cut profoundly into its sides, and laying bare the centre to a depth of from 2000 to nearly 4000 feet below the existing summit. As shown on the accompanying map, the valleys, due to erosion, are so crowded on one another, that the dissection is complete, thus disclosing the inner structure of a great volcanic mountain. The interior is shown to be composed, not of lava-beds, there being no horizontal lines, but of imperfect columnar formations, rising vertically in the unstratified mass quite to the summit. The uniform massiveness through so great a height at the volcano's centre is attributed to the cooling of continuously liquid lava in the region of the great central conduit of the cone. A comparative study of Mauna Loa (Hawaii), shows that such a massive central structure is a common feature of the *greater* volcanic mountains, the extremely slow cooling process under great pressure causing the lava to solidify into a *compact* crystalline rock, and often into a *coarsely crystalline* rock.—Origin of the ferruginous schists and iron ores of the Lake Superior region, by R. D. Irving. Rejecting the igneous theory, now held by few, the writer, after a careful survey of the whole field, concludes that these rocks were once carbonates analogous to those of the coal-measures, which by a process of silicification were transformed into the various kinds of ferruginous formations now occurring in this region.—Further notes on the artificial lead silicate from Bonne Terre, Montana, by H. A. Wheeler. An analysis of this interesting substance, which was found under the hearth of an old reverberatory roasting-furnace, yielded 73·66 PbO, 17·11 SiO_2, NiO 3·06 (coarse crystals), 72·93 PbO, 18·51 SiO_2, and smaller quantities of nickel, cobalt, and other ingredients.—Limonite pseudomorphs after pyrite, by John G. Meem. The paper gives a short account of the pseudomorphs occurring in Rockbridge County, Virginia, where they are associated with Lower Silurian limestones. These crystals, varying in colour from a very light to a very dark brown, and sometimes almost black, are hydrous, and yield a yellow powder, showing them to be limonite, most commonly of octahedral form.—Note on the hydro-electric effect of temper in case of steel, by C. Barus and V. Strouhal. The object of this inquiry is to determine directly the carbon relations of steel as a function of the temperature (0° to 400°, 400° to 1000°) and of the time of annealing, with full reference to the physical occurrences observed in the first and second phases of the phenomenon.—On the crystalline structure of iron meteorites, by Oliver Whipple Huntington. It is shown that the usual classification of these meteorites into octahedral and cubic crystals cannot be natural or fundamental. A careful examination of the large collection belonging to Harvard College, containing types of all the characteristic meteorites of this class, leads to the conclusion that masses of meteoric iron are cleavage crystals, broken off probably by impact with the air, and showing cleavages parallel to the planes of all three fundamental forms of the regular system (octahedron, cube, and dodecahedron); further, that the Widmanstättian figures and Neumann lines themselves are sections of planes parallel to these same forms, exhibited in every gradation from the broadest bands to the finest markings, with no natural break, the features of von Widmanstätten's figures being, moreover, due to the eliminations of impurities during the process of crystallisation.—A new meteoric iron from Texas, by W. Earl Hidden. The specimen here described and illustrated was discovered by Mr. C. C. Cusick on June 10, 1882, near Fort Duncan, Maverick County, Texas. It weighs over 97 pounds, is quite soft, being easily cut with a knife, and consists of iron 94·90; nickel and cobalt, 4·87; phosphorus, 0·25, with traces of sulphur and carbon; specific gravity, 7·522.—On pseudomorphs of garnet from Lake Superior and Salida, Colorado, by S. L. Penfield and F. L. Sperry. The Lake Superior specimen is essentially an iron alumina garnet, with formula $Fe_2Al_2Si_3O_{12}$. That of Colorado is higher in protoxides and water, the increase being perhaps due to the presence of ripidolite.—Further notes on the meteoric iron from Glorieta Mount, New Mexico, by George F. Kunz.—On the Brookite from Magnet Cove, Arkansas, by Edward S. Dana. These crystals, first described in 1846 by Shepard under the name of *arkansite*, are especially remarkable for the great variety of their forms, which is most unusual for crystals occurring in the same locality.

SOCIETIES AND ACADEMIES

LONDON

Zoological Society, November 16.—Prof. W. H. Flower, F.R.S., President, in the chair.—An extract was read from a letter addressed to the President by Dr. Emin Bey, dated Wadilai, Eastern Equatorial Africa, January 1, 1886, and containing some notes on the distribution of the Anthropoid Apes in Eastern Africa.—A letter was read, addressed to the Secretary by Dr. Chr. Lütken, of Copenhagen, F.M.Z.S., containing some information as to the locality of *Chiropodomys penicillatus*.—A letter was read from Dr. A. B. Meyer, C.M.Z.S., communicating some remarks by Mr. K. G. Henke on a specimen of a hybrid Grouse in the Dresden Museum.—Prof. Flower, F.R.S., exhibited and made remarks on a specimen of a rare Armadillo (*Tatusia pilosa*) belonging to the Scarborough Museum.—Prof. Bell exhibited, and made remarks on, an object (apparently of the nature of an amulet) made from a portion of the skin of some mammal, and received from Moreton Bay, Australia.—Mr. H. Seebohm, F.Z.S., exhibited a skin of what he considered to be a young individual of the Lesser White-fronted Goose (*Anser albifrons minutus*), shot in September last on Holy Island, off the coast of Northumberland, and observed that it was the first recorded example of the small form of the White-fronted Goose which had been obtained on the coasts of our islands.—Mr. Blanford, F.R.S., exhibited, and made remarks on, a mounted specimen of a scarce Paradoxure (*Paradoxurus jerdoni*) from the Neilgherry Hills in Southern India.—A communication was read from Colonel Charles Swinhoe, F.Z.S., containing an account of the species of Lepidopterous insects which he had obtained at Mhow, in Central India.—A communication was read from Dr. R. W. Shufeldt, C.M.Z.S., containing an account of the anatomy of *Geococcyx californianus*.—Mr. Lydekker described three crania and other remains of *Scelidotherium*, two of the former being from the Argentine Republic, and the third from Tarapaca, in Chili. One of the crania from the first locality he referred to the typical *S. leptocephalum* of Owen, while the second, which had been described by Sir R. Owen under the same name, he regarded as distinct, and proposed to call *S. bravardi*. The Tarapaca form, which was characterised by the extremely short nasals, was also regarded as indicating a new species, for which the name of *S. chilense* was proposed. The author concluded that there were not sufficient grounds for separating Lund's proposed genus *Platyonyx* from *Scelidotherium*.—Mr. G. A. Boulenger pointed out that two distinct forms of the Batrachian genus *Bombinator* occur in Central Europe, and read notes on their distinctive characters and geographical distribution.—A communication was read from Dr. R. W. Shufeldt, containing a correction, with additional notes, upon the anatomy of the *Trochili*, *Caprimulgi*, and *Cypselidæ*.—A communication was read from Dr. R. A. Philippi, C.M.Z.S., containing a preliminary notice of some of the Tortoises and Fishes of the coast of Chili.—Mr. Sclater exhibited the head of, and made remarks upon, an apparently undescribed species of Gazelle from Somali Land.

Geological Society, November 3.—Prof. J. W. Judd, F.R.S., President, in the chair.—Henry Howe Arnold-Bemrose, Richard Assheton, Francis Arthur Bather, Rev. Joseph Campbell, M.A., John Wesley Carr, Thomas J. G. Fleming, Thomas Forster, Edmund Johnstone Garwood, George Samuel Griffiths, Dr. Frederick Henry Hatch, Ph.D., Robert Tuthill Litton, Frederick William Martin, Richard D. Oldham, Forbes Rickard, Albert Charles Seward, Herbert William Vintner, and Charles D. Walcott were proposed as Fellows of the Society.—The following communications were read:—On the skull and dentition of a Triassic Saurian, *Galesaurus planiceps*, Ow., by Sir Richard Owen, K.C.B., F.R.S. The author referred to a fossil skull from the Triassic sandstone of South Africa, which combined dental characters resembling those of a carnivorous mammal with the cranial structure of a Saurian. The structure was described and figured in Owen's "Catalogue of the Fossil Reptilia of South Africa," under the generic title of *Galesaurus*, as belonging to a distinct sub-order of Reptilia termed *Theriodontia*. The characters of the skull and teeth of the original specimen of *Galesaurus* have been brought to light by further development. In both the type-specimen and that lately received, the reptilian nature of the fossil is indicated by the single occipital condyle and other features. The chief difference from a mature male of a placental or marsupial carnivore is the evidence of a primordial "gullet-tract." Further details as to the structure of the skull were given, more especially with reference to the orbits and nasals. The palatal region repeats the same general characters as in previously described Theriodonts. The angle of the jaw is not produced, as in the crocodile, beyond the articular element. In general shape and bony strength the mandible of *Galesaurus* resembles that of a mammal. The dentition is so much better preserved in the new specimen than in the type Galesaur as to call for description and illustration. In four of the upper molars the entire crown is preserved; it shows less length and greater breadth than appears in the previous restoration, is moderately curved externally, and triangular; the base is flanked by a short cusp before and behind, and the corresponding margins are finely crenulate, as in the molars of *Cynodracon*. The incisors are eight in number in both upper and lower jaws, four in each premaxillary, opposed or partially interlocking with the same number in each mandibular ramus; they have longish, slender, simple-pointed crowns. The canines, one on each side of both upper and lower jaws, have the same laniariform shape and size of crown as in the original fossil. In the right maxillary bone the long deeply-planted root is exposed; the corresponding part of the lower canine is similarly exposed in the left mandibular ramus. No trace of successional teeth, as in ordinary Saurians, has been found. Both crocodiles and alligators have two or more teeth of canine proportions; but the author shows how they differ from those of mammalian carnivores and *Galesaurus*. A similar character and disposition of destructive canines is shown by the fossil jaws of the oolitic great extinct carnivorous Saurians, *e.g.* *Megalosaurus*. In the Triassic Labyrinthodonts the destructive and prehensile laniaries would, by position, rank as incisors rather than canines. In existing lizards the dental series has more uniformity, and the cement-clad roots contract bony union with the jaw-bone. In *Galesaurus* the teeth, besides being distinguished, as in mammals, by their differential characters, are implanted freely in sockets, the cold-blooded character being chiefly manifested in the greater number of teeth following the canines, and in their want of distinction. Lastly, the author remarked on the earlier reptilian character shown by the oolitic mammal *Amphitherium*, and also by the existing Australian *Myrmecobius*. He speculates on the degree of resemblance manifested by the teeth of the old Triassic reptile of South Africa with the exceptional characters of some of the low Australian forms of mammals.—The Cetacea of the Suffolk Crag, by R. Lydekker, B.A., F.G.S. This paper commenced with notices of previous contributions to the subject by Sir R. Owen, Prof. Ray Lankester, Prof. Huxley, and Prof. Flower. In the preparation of a catalogue of the specimens in the British Museum, the author had had occasion to examine the collection of Cetacea from the Crag, not only in that Museum, but also in the Museum of Practical Geology, that of the Royal College of Surgeons, and in the Ipswich Museum, besides visiting the collections at Brussels. In consequence, several additions to the fauna, and also numerous emendations of specific names, were noticed in the paper now laid before the Society. Prof. Ray Lankester's views as to the Diestian affinities of the English-Crag Cetacea were confirmed by this comparison. Detailed notes on the specimens examined and the species identified were given.—On a jaw of *Hyotherium* from the Pliocene of India, by R. Lydekker, B.A., F.G.S. Colonel Watson, the Political Resident in Kattiawar, had recently sent to the author a fragment of a left maxilla with the three true molars, from Perim Island, in the Gulf of Cambay. The specimen belonged to *Hyotherium*, and apparently to an undescribed species, the differences between which and the several forms previously known from various European and Asiatic beds were pointed out. The author also called attention to the peculiar association of types found in the beds of Perim Island, and to the affinities of the genus *Hyotherium* with the recent *Sus* and *Dicotyles* on the one hand, and with the Upper Eocene *Chœropotamus* on the other.

Physical Society, November 13.—Prof. Balfour Stewart, President, in the chair.—In opening the proceedings, the President referred to the great loss which the Society had recently sustained by the death of Prof. Guthrie, F.R.S., the founder of the Society, and his predecessor in the chair. In the capacity of Demonstrator, Prof. Guthrie contributed materially to the success of the Society's meetings, and his decease is deeply regretted. The President also announced that the Council were considering what steps should be taken to commemorate the late Dr. Guthrie, and that a circular containing their views would be placed before the members in the course of a few days. —The following papers were then read:—On the peculiar sunrise shadows of Adam's Peak, in Ceylon, by the Hon. Ralph Abercromby, F.R.Met.Soc. The author prefaced his description by an extract from a paper on the same subject by the Rev. R. Abbay, read before the Physical Society, May 27, 1876, in which the explanation proposed is that the effects are caused by total internal reflection, as in ordinary mirage, the difference of air-density being, in this case, due to the lower temperature at high altitudes. The author pointed out that Mr. Abbay neglects the difference of density due to elevation, and that his own thermometric observations disprove conclusively any idea of mirage. The chief phenomena observed were: (1) the appearance of a circular rainbow with spectral figures near the top of the shadow of the peak; and (2) a peculiar rising of the bow and shadow, which seem to stand up in front of the observers. Both these effects are traced to the existence of mist-clouds in the vicinity of the shadow. Two dark rays or brushes were seen to shoot outwards and upwards from the circumference of the bow in directions nearly coinciding with the prolongations of the edges of the shadow, when seen projected on the lower mist-clouds, but the author does not attempt to explain this phenomenon. On one occasion a second and outer bow was seen. The times during which the phenomena were visible were too short to permit sextant observations being taken, but the diameter of the inner bow was estimated at 8° to 12°. A totally distinct kind of shadow is sometimes seen from Adam's Peak just before, and at the moment of sunrise, which seems to stand up against the distant sky. The author found a similar effect at Pike's Peak, Colorado, which is visible only at sunset. Mr. G. Griffiths remarked that he had often seen similar appearances in Switzerland. In answer to questions by the President and Prof. S. P. Thompson, the author said the reason why the shadows were seen from Adam's Peak at sunrise, and from Pike's Peak at sunset, was that the configuration of the land on the west side of the former was similar to that on the east side of the latter, both being low, whereas the opposite sides were high, and therefore unsuitable for showing the phenomena. In all cases he believed the appearances were due to the shadows being projected on clouds of suspended matter in the air at various altitudes. He had not noticed whether the colours were reversed in the second bow seen from Adam's Peak, but observed that this bow nearly, but not quite, touched the inner one.—Note on the internal capacity of thermometers, by A. W. Clayden, M.A. (Read by Prof. Reinold, Secretary.) The author proposes to determine the volume, V, of the mercury by measuring the capacity, c, of a detached piece of the same tube of known length, and thence inferring the volume of t degrees of the thermometer tube, the length of which is equal to that of the piece of tube taken. By assuming the value of a (the coefficient of *apparent* expansion of mercury in the particular kind of glass) to be known, the volume of the mercury in the thermometer can be calculated, since $c = t\,a\,V$. Prof. Rücker remarked that there were often considerable differences in the sectional area of different parts of the same tube, and hence the method would probably not be very reliable.—On the motion of the President, a vote of condolence to Mrs. Guthrie in her sad bereavement was passed unanimously.

Royal Meteorological Society, November 17.—Mr. W. Ellis, F.R.A.S., President, in the chair.—The following were elected Fellows:—Mr. B. A. Dobson, Mr. T. Gordon, Mr. H. Mantle, Rev. J. Watson, and Mr. F. Wright.—The papers read were:—The gale of October 15–16, 1886, over the British Islands, by Mr. C. Harding, F.R.Met.Soc. The storm was of very exceptional strength in the west, south-west, and south of the British Islands, but the principal violence of the wind was limited to these parts, although the force of a gale was experienced generally over the whole kingdom. By the aid of ships' observations, the storm has been tracked a long distance out in the Atlantic. It appears to have been formed about 250 miles to the south-east of Newfoundland on the 12th, and was experienced by many ocean steamers on the 13th. When the first indication of approaching bad weather was shown by the barometer and wind at our western outposts, the storm was about 500 miles to the west-south-west of the Irish coast, and was advancing at the rate of nearly 50 miles an hour. The centre of the disturbance struck the coast of Ireland at about 1 a.m. on the 15th, and by 8 a.m. was central over Ireland. The storm traversed the Irish Sea, and turned to the south-east over the western Midlands and the southern counties of England, and its centre remained over the British Isles about 34 hours, having traversed about 500 miles. The storm afterwards crossed the English Channel into France, and subsequently again took a course to the north-eastwards, and finally broke up over Holland. In the centre of the storm the barometer fell to 28·5 inches; but, as far as the action of the barometer was concerned, the principal feature of importance was the length of time that the readings remained low. At Geldeston, not far from Lowestoft, the mercury was below 29 inches for 50 hours, and at Greenwich it was similarly low for 40 hours. The highest recorded hourly velocity of the wind was 78 miles, from north-west, at Scilly on the morning of the 16th; but, on due allowance being made for the squally character of the gale, it is estimated that in the squalls the velocity reached for a minute or so the hourly rate of about 120 miles, which is equivalent to a pressure of about 70 lbs. on the square foot. On the mainland the wind attained a velocity of about 60 miles an hour for a considerable time; but, without question, this velocity would be greatly exceeded in the squalls. In the eastern parts of England the velocity scarcely amounted to 30 miles in the hour. The force of the gale was very prolonged. At Scilly the velocity was above 30 miles an hour for 61 hours, and it was above 60 miles an hour for 19 hours, whilst at Falmouth it was above 30 miles an hour for 52 hours. The erratic course of the storm and its slow rate of travel whilst over the British Islands were attributed to the presence of a barrier of high barometer readings over Northern Europe, and also to the attraction in a westerly direction, owing to the great condensation and heavy rain in the rear of the storm. The rainfall in Ireland, Wales, and the south-west of England was exceptionally heavy. In the neighbourhood of Aberystwith the fall on the 15th was 3·83 inches, and at several stations the amount exceeded 2 inches. Serious floods occurred in many parts of the country. A most terrific sea was also experienced on the western coasts and in the English Channel, and the number of vessels to which casualties occurred on the British coasts during the gale tell their own tale of its violence. The total number of casualties to sailing-vessels and steam-ships was 158, and among these were five sailing- and one steam-ship abandoned, five sailing- and one steam-ship foundered, and forty-two sailing- and two steam-ships stranded. During the gale the life-boats of the Royal National Life-boat Institution were launched fourteen times, and were instrumental in saving thirty-six lives.—The climate of Carlisle, by Mr. T. G. Benn, F.R.Met.Soc. This is a discussion of the observations made at the Carlisle Cemetery. The mean temperature for the twenty-three years (1863–85) was 47°·5; the absolute highest was 95° on July 22, 1873, and the lowest −5°·5 on January 16, 1881. The mean annual rainfall was 29·80 inches; the greatest monthly fall was 7·84 inches in July 1884, and the least 0·30 inches in January 1881. The average number of rainy days was 174.—Results of hourly readings derived from a Redier barograph at Geldeston, Norfolk, during the four years ending February 1886, by Mr. E. T. Dowson, F.R.Met.Soc.—Results of observations taken at Delanasau, Bua, Fiji, during the five years ending December 31, 1885, with a summary of results for ten years previous, by Mr. R. L. Holmes, F.R.Met.Soc.

Anthropological Institute, November 9.—Mr. Francis Galton, F.R.S., President, in the chair.—The election of the following new Members was announced:—G. W. Hambleton, D. F. H. Hervey, W. R. Reid, M.D., R. J. Ryle, M.A., M.B., and W. F. Stanley, F.G.S.—Prof. Flower exhibited some of Dr. Otto Finsch's casts of natives of the Pacific Islands, and made some general remarks on the collection.—A paper by Dr. E. T. Hamy, entitled "An Interpretation of one of the Copan Monuments," was read. In this paper the author traced a resemblance between the symbol found upon a large and regular convex stone at Copan and the Chinese "Taï-Ki," and argued that the presence of such a symbol in the ruins of Copan, where there exist so many manifestations of a strange and curious art so closely allied to the Eastern arts of the Old World, furnishes a fresh proof in support of the theory of an Asiatic influence over American civilisation.—An exhaustive paper by Mr. H. Ling Roth, on the aborigines of Hispaniola, was read.

SYDNEY

Linnean Society of New South Wales, September 29.—Prof. W. J. Stephens, M.A., F.G.S., President, in the chair.—The following papers were read:—A revision of the Staphylinidæ of Australia, part ii., by A. Sidney Olliff, F.E.S., Assistant Zoologist, Australian Museum. This part, containing the members of the sub-family, *Tachyporinæ*, is another contribution to a general revision of the family. No marked Australian forms have been found, and the new forms are of the ordinary type. The genera *Tachyporus*, *Tachinus*, and *Bolitobius*, are added to the Australian fauna. With this instalment is issued the plate (vii.), which would have accompanied the first part, but for an unfortunate accident to the artist.—Notes on the bacteriological examination of water from the Sydney supply, No. I., by Dr. Oscar Katz.—On a remarkable Bacterium (Streptococcus) from wheat-ensilage, by Dr. Oscar Katz. This paper contains a brief description of a Micrococcus (Streptococcus), obtained from a sample of mouldy wheat-ensilage which, some time ago, it will be remembered, came under public notice in connection with an epidemic which attacked some horses at Coonong, N.S.W. This micro-organism shows characteristic features in its pure cultivations on or in different nutrient soils. Inoculations of this and other microbes found in the samples are intended to be made shortly upon living animals.—Notes on *Lindsea trichomanoides* and *Eriostemon Crowei*, by the Rev. W. W. Woolls, M.A., Ph.D. Dr. Woolls makes some remarks on the first of these, a fern common in New Zealand, but not recognised until of late in New South Wales. He also exhibited a specimen of *Crowea exalata* (*E. Crowei*, v. M.) from the Currajong, and showing marked differences from the *C. saligna* of the flora. Mr. Bettche, however, of the Botanic Gardens, had collected a specimen which was distinctly intermediate, and which probably may unite the two species, *E. salignus* and *E. exalatus* again, according to the Baron's first determination.—Note on a Labyrinthodont fossil from Cockatoo Island, by Prof. Stephens, M.A. The President read a notice of a fossil Labyrinthodont, probably *Mastodonsaurus* sp., recently found at Cockatoo Island, and pointed out the conclusions to which this fossil, the *Ceratodus* of Queensland, and the *Hatteria* of New Zealand, lead in regard to the ancient geographical conditions of the southern hemisphere.—Notes on Australian earthworms, part ii., by J. J. Fletcher, M.A. In this paper descriptions are given of nine new species of earthworms, of which five are indigenous to New South Wales, one is supposed to have been introduced from the Mauritius, two are from Queensland, and one is from Darnley Island, Torres Straits. They include a new species of Perrier's genus *Digaster*, a new species of *Cryptodrilus*, and seven species of *Perichæta*. The last-named are separable into two well-marked groups: the one characterised by the possession of complete circles of setæ, and by the presence of two cæcal appendages of the large intestine in segment xxvi.; the other characterised by having incomplete circles of setæ, and no intestinal cæca. To the first group belong the species from North Queensland and Darnley Island; and the introduced species. Remarks are also made upon a few worms from Percy Island, which were collected during the Chevert Expedition, and which are now in the Macleay Museum, but are immature or not sufficiently numerous to admit of satisfactory description.—Notes on some New South Wales fishes, by Dr. Ramsay, F.R.S.E., and J. Douglas-Ogilby. The common Jew Fish of Port Jackson is here described under the name of *Sciæna neglecta*, the authors pointing out the marked differences between it and *S. antarctica*, Castelnau, and *S. aquila*, Lacep., the species to which it has been hitherto referred. Evidence is also given that *Callionymus reevesii*, Rich., is not, as has been stated, the female of *C. curvicornis*, C. and V.

PARIS

Academy of Sciences, November 15.—M. Jurien de la Gravière, President, in the chair.—Letters having been read from M. de Freycinet announcing the death of M. Paul Bert, Resident-General in Annam and Tonquin, and Member of the Academy, the President and M. Vulpian followed with some remarks on the great services rendered to science by this distinguished physiologist. Reference was made more especially to his researches on the action of light on living organisms; on the physiology of respiration; and on the influence exercised on man, animals, plants, and ferments, by increased or diminished pressure of atmospheric air, of carbonic acid, and of oxygen.—Observations of the small planets made with the large meridian instrument of the Paris Observatory during the second quarter of the year 1886, communicated by M. Mouchez. Numerous observations made by M. P. Puiseux on Pallas, Juno, Olympia, Electra, Urania, Europa, and several other minor planets, are here brought into relation with the ephemerides either of the *Nautical Almanac*, the *Bulletin Astronomique*, or the Berlin *Jahrbuch*.—Researches on the phosphates, by M. Berthelot. Fresh researches are here reported on the double decompositions which reveal in the insoluble tribasic phosphates the existence of two distinct states: one colloidal, amorphous, unstable, answering to the manifold constitution of the soluble phosphates; the other crystallised and stable, in which the three basic equivalents seem on the contrary to play the same part. The phosphates of soda, magnesia, baryta, lime, manganese, and the tribasic phosphates of strontian are specially considered.—Observations of Winnecke's comet, by M. L. Cruls. As observed during last September at the Observatory of Rio de Janeiro, this comet presented the appearance of a nebulosity about 2′ in diameter, without clearly-defined nucleus, of somewhat circular form and slight luminous intensity.—Note on Abel's theorem, by M. G. Humbert.—On the flow of a gas penetrating into a receptacle of limited capacity, by M. Hugoniot. The question here dealt with is to determine the time required to fill a receptacle containing air at an initial pressure p_0, and placed in communication with a reservoir maintained by compressing-engines at a constant pressure $p_1 > p_0$. The reading of the paper was followed by some remarks by M. Haton de la Goupillière on this fresh confirmation of his own theories on the flow of gases.—On the variation of the magnetic field produced by an electromagnet, by M. Leduc. Reference is made to M. Marcel Deprez's communication of October 26, which partly confirmed the conclusions already arrived at by the author, and announced to the Société de Physique on February 19, 1886. But the results obtained present considerable numerical differences, which may be due to the different conditions under which the experiments were made.—On the specific inductive power and conductivity of dielectrics: relation between conductivity and absorbing power, by M. J. Curie.—On the velocity of dissociation, by M. H. Lescœur. It is shown that the results drawn from the velocity of dissociation may supply valuable data regarding the presence of the hydrates and analogous compounds; but they can give no absolute or relative indications respecting the tensions of dissociation.—On some laws of chemical combination, by MM. de Landero and Raoul Prieto. In these studies, of which a few preliminary essays are here communicated, chemical combination is regarded as resulting from the shock of a collision between the particles of the elements forming any given compound. The velocity of the particles in motion being considered as a characteristic constant of each body, the loss of energy or of vital force due to the shock between non-elastic particles is regarded as the equivalent of the quantity of heat liberated by the fusion.—On some histological peculiarities of the acephalous mollusks, by M. Louis Roule.—On the typical nervous system of the ctenobranch mollusks, by M. E. L. Bouvier.—On platyrhinism in a group of African apes, by M. A. T. de Rochebrune. It is shown that the family of the Colobi forms a marked exception to the general rule that the apes of the Old World are all catarhinous. As already anticipated by Dahlbom and Gray, they prove to be distinctly platyrhinous, like all the American Simiæ.—Experimental researches on the synthesis of the lichens in a medium destitute of germs, by M. Gaston Bonnier. The researches carried out by the author since 1882 have resulted in the complete reproduction by synthesis of a certain number of species of lichens under conditions fully confirming the views generally held regarding the complex nature of these vegetable organisms. The results clearly show that a lichen is formed by the association of an Alga and a fungus.—The avifauna of the Mentone caves, by M. Émile Rivière. Of the forty-two species found in these caves, all still survive except *Pyrrhocorax primigenius*, but their present distribution mostly differs from that of Quaternary times, many having disappeared from the Mentone district, owing to climatic changes, the destruction of forests, and the chase.—On the Jurassic Echinidæ of Lorraine, by M. G. Cotteau. The researches made by the author in this branch of palæontology show that in Lorraine the Echinidæ followed the same line of development as in other Jurassic regions.—A physiological study of the respiratory function in singers, by M. Anatole Piltan. Observations made in various institutes show that the quality of the voice is inherent to the expiratory type adopted by the subject, whether unconsciously or acquired by special training.—Bacteriological studies on the Arthropods, by M. Balbiani.

THURSDAY, DECEMBER 2, 1886

INDUSTRIAL EDUCATION IN AMERICA

Industrial and High Art Education in the United States. Part I. "Drawing in Public Schools." By J. Edwards Clarke, A.M. (Washington: Government Printing Office, 1885.)

CHANGES required in school training, in the substance as well as in the method of it, are now felt to be a vital question to the political economist and the law-maker, as well as to the moralist. While the old apprenticeship system was in its vigour, the youth was taught at school the three R's and whatever other branches of a liberal education his parents could afford, and for seven years after that technical instruction was given to him in all the branches of the trade he had chosen by his master, the best teacher that could be found in those days. But under the influence of machinery that system has completely collapsed, and the feeling is rising everywhere that something must be done at school to replace instruction given of old by the master. Theorists insist that nothing short of a technical school, where each trade is taught from beginning to end, will sufficiently replace the care and the interest of the latter, and they hold up the Russian Strogonoff school as an example of their being taught in this complete way and triumphantly compare its work with that of the best manufacturing countries. They urge that in a system of public education like that of the United States it is a serious fault that, while a classical or professional education is provided free for the youth who desires it, technical instruction is denied to a far larger body of mechanics who have as perfect a claim to the education they require. In Stockholm the experiment of every elementary school having a carpenter's and joiner's shop attached is being tried, but the impracticability of carrying on in every town schools where instruction in each art can be efficiently given to the labouring classes has left the teaching of theorists little else but theory, and a technical school giving instruction in the one or two principal trades of a district is all that can be looked for.

One item of education, however, has made its way in most European countries, as being a help to all technical work, encouraging observation and correctness, and enabling such observation to be registered and expressed. It is here asserted to be a qualification for nine-tenths of the occupations into which all labour is divided, and is welcomed by the most advanced supporters of technical schools as the first step. Reading, writing, arithmetic, and drawing are now to be the four fundamental studies. A knowledge of it is essential in many of the studies in the schools of science, and especially useful to all engaged in the profession of teaching. More doubtful assertions are that like other technical teaching it does not necessarily interfere with or hinder other work, and that it positively assists in learning to write; this latter having the authority of the London School Board, as well as that of an American writer quoted in this volume. The rise in value also in the labour-market of each mechanic who has the power to draw or even understand a drawing of a mechanical arrangement is often insisted upon; but when such an accomplishment has become common to all, and therefore gives its possessor no superiority, this is rather doubtful, though the raising of a whole class to the capacities of artists and engineers will very likely add to republican equality.

While England has for years encouraged the teaching of drawing, and, the year before last, made it a part of the education of all boys in elementary schools, in the United States a sense of its importance has been only slowly making its way. Recently, however, the Senate requested all information on the subject of industrial and high art education in the United States to be laid before it by the Education Bureau. This work was committed to Mr. J. Edwards Clarke, already the author of a Circular on the subject published in 1874, which excited so much interest and drew so much further information that it is reproduced at p. 487 of this volume, having now, the author claims, some little historical interest, the meagre list which it contains of art institutions in the country at that date contrasting with the changes already brought about. The Bureau had already decided to prepare a much more comprehensive work, which should combine a history of the earliest efforts of writers of all views in all parts of the United States and in England; an account of their failures and successes, and especially of the Massachusetts success; with information as to planning schools of high art and public art-museums; lists of art-publications and materials; extracts from foreign official reports as well as from other foreign material. This, even before the Senate's Commission enlarged its scope, was sufficient to make a tolerably voluminous work. But a source of disorder and much repetition has been a series of delays in its publication. It was complete for publication in 1877, and while in one article of that date criticising the few artistic buildings which New York could show in 1875, it rejoices in a later one at the improvement there in 1883, and the artistic taste displayed by its architects; it was ready again in 1880; corrected again for 1882, and statistical tables down to 1881–82 printed, which again it is promised shall be supplemented by tables reaching down to June 30, 1885, at the end of the fourth volume to which this work is to reach. It was printed in 1885, and inserts publications of that year, yet quotes from an "unpublished" report of the National Educational Association held in 1884; and it is still only promised to the public at this year's end. Since this one volume extends to 1100 pages of, for the most part, small-printed matter, the whole work may be looked upon as an encyclopædia of information bearing upon the drawing question, of value chiefly to two classes of men, viz. school teachers, who will find nothing wanting, and earnest advancers of art education. For unless the general public in America be far different from our own they will not be *led* into the study of the subject by such a publication as this, and in its present form it must quite fail of the general effect upon them aspired to on p. xxx. The fourteen papers by the compiler with which the work opens would be appropriate for rousing attention if dispersed over the country in the most handy form; in their present position their inflated and impetuous style is inconsistent with the idea of exactness to be expected in this class of publication.

As late as 1876 the introduction of drawing into the public schools was looked upon as a novel project in the United States; for while Mr. Clarke considers that England has spent "an enormous aggregate of money in the work" the Americans, so profuse in other educational expenditure, have been strangely apathetic in the matter. One explanation given is that during the Middle Ages the Church and the aristocracy were the great patrons of high art, and this bred an instinctive dislike to its pursuit in the minds of New England emigrants. But besides the delineation of Nature and of all her forms of beauty, the minister of cultivated wealth and luxury, there is another branch of drawing of the highest importance to nearly every mechanic in these days, viz. geometrical drawing, the foundation of all industrial art, leading up to the elaborate perspective of a complicated machine. Both branches are of course required in many manufactures. Which shall be pursued with most energy in any town must depend upon its staple trades; in some few businesses, as in watches and woven fabrics, the mechanical and the ornamental have about equal claims. The same idea, that drawing meant ornamental art alone, and that its chief results would be the sort of things that accomplished young ladies bring home after a few terms of learning drawing, established itself in the minds of the ratepayers. To meet this the general tone of quotations through this report is that "industrial drawing is of the most practical nature, and has nothing to do with pictures of old ruins, landscapes, &c." Yet elsewhere Mr. Clarke is most contemptuous towards any who wish to confine the drawing taught in any school to "that part of it directly related to industrial interests"; and the teaching of the self-willed Haydon, of whom he gives a long account as the victim of cruel and ignorant persecution of "aristocratic connoisseurs" but as an apostle of art to the common people, is just as confidently quoted with no qualification. Haydon's teaching is that the study of the nude human figure is the best qualification of an artist for any manufacturing business, and every one holding a different opinion is dismissed by Mr. Clarke with contempt. This necessity for high art teaching is a hard doctrine, and certainly discouraging to those who hope to qualify a majority of the working classes for artistic producers or intelligent machinists. Perhaps it only resolves itself into the explanation given on p. 482 by Mr. Sparkes, and supported also by the quotation from Mr. William Morris, that the greater includes the less, and that if an artist is well able to delineate the "subtle lines" of the human figure in a complex attitude, he is not likely to fail in working up a lily or a rose; and this is only in accordance with Mr. Stetson's teaching quoted on p. 649. Still a superiority of French over German art designs is attributed to the former making the human figure their first study and then proceeding to flowers and ornament, while the latter take what seems to us the more natural course of the reverse order.

In 1870 the State of Massachusetts after inviting various experts to express their opinions (here reported) decided that drawing should be taught in all its schools. The larger part of this bulky volume is directly or indirectly the history of the call of Mr. Walter Smith, head master of the School of Art at Leeds, who was recommended by Sir Henry Cole to be intrusted with the management of the whole matter. There are 120 closely-printed pages devoted to his work in Massachusetts as Art Director from 1871. Every part of the subject was under his guidance, and to impress upon the reader the amount of work entailed upon him an additional chapter is added to describe the unsatisfactory state of things in Boston before his arrival. The whole of his first report for 1872 is given, and long extracts from each yearly report on normal schools and every other department afterwards. Plans of instruction for evening classes which he superintended, as well as of teaching in school hours, are quoted in full. To advance his subject he took to the principal towns in the State a travelling museum of models and examples for study, many supplied from South Kensington. In one appendix are given copious extracts from an address delivered by him to the Pennsylvania Legislature in 1877 on behalf of the Museum and School of Industrial Art of that State; in another practical papers on drawing, chiefly by him, of value of course to managers who have just succeeded in introducing the teaching of drawing; three lectures delivered respectively to the teachers of the three grades of elementary, grammar, and high schools; followed by extracts from similar addresses delivered, after his connection with Massachusetts had ceased, at Montreal and Quebec.

The chief difficulty of course in setting such a work going was the scarcity of teachers, and this remained a difficulty up to the last. A paper accordingly by General Francis A. Walker, describing drawing as the foundation of all technical education, urges that the normal school should in truth precede, not follow, the elementary school. Another difficulty which an Association of Teachers found, and which showed the state of things at that time, was that there was so great a scarcity of art-books in the country that the Association set itself to encourage the reprinting, translation, and publication of such books.

On the whole, the energy inspired and the method introduced were so successful in Massachusetts that we are told that its history will form a lasting monument alike to the genius of Walter Smith and to the far-reaching foresight of the school authorities and State Legislature in 1872–73.

Appendix D is an account of the differences which rose between the Committee of Education in Massachusetts and Prof. W. Smith. The latter has now returned to England and taken the head mastership of the Art Department of the Technical College at Bradford. Great regrets are expressed at the, to them, untimely event of his resignation, and it is lamented that he should return from leading the industrial education of a continent to an English provincial college! The work now (1883) is reported as in too few hands, though still progressing from the impetus it had received.

No other States have gone into art education with the energy which Massachusetts displayed in 1872. Two others only, New York and Maine, have required that it shall be taught in all schools. In the latter it is urged as the more important, because every natural feature of the country points it out as the seat of manufactures and not of agriculture. But neither Maine nor New York has provided a normal school for the training of teachers. In various other States, however, individual cities have adopted drawing and made it a regular part of the course.

Syracuse, in the State of New York, can boast a priority in this good work even over Boston.

Though speaking everywhere most bitterly of England, —an Americanism so out of date now that happily it is more comical than irritating, especially when he goes so far as to call the great works on political economy which have made their way over the whole civilised world "emissaries of English policy which she has succeeded in introducing,"—the writer everywhere holds up England as an example in art education. The whole of the work is credited to Sir Henry Cole and South Kensington, although there were twenty Government-supported Schools of Design in England in 1847. Still the writer cannot resist the sneer that there would have been no art-teaching in England if a Royal Prince had not urged it! But many times over he relates how visitors were struck with the clumsy inartistic style of all English art-work at the Exhibition of 1851 compared with that of many foreign nations, and the good result of an energetic and most successful effort by the nation to remedy it is constantly urged as appearing at the Philadelphia Exposition of 1876. There the Americans found themselves as far behind England as England had been behind other European countries in 1851, through the inartistic ignorance of their manufacturing classes. Many practical lessons and suggestions were there supplied to them, and much of this volume is a record of their influence. Appendix E gives a lengthy paper by Mr. Stetson reviewing the work exhibited there by all the various foreign nations and by each of the American towns, and it records the influence of this Exhibition upon industrial art. We should like to have heard something, however, of the result of the New Orleans Exhibition, no report of which has reached us, although so much was promised.

While anxious by making drawing general to "utilise all the pleasure which a slate and pencil give a child," Mr. Clarke's unqualified love of liberty makes him object to infringing on even a child's freedom, and actually trusts to the extra interest that many gutter children would take in gaining technical skill to render compulsion unnecessary. He urges with good reason that nowhere would artistic skill be so well rewarded as in the United States during its present rapid rise in wealth as well as in population, and that skilled art labour is far more valuable than the labour bestowed upon plainer, rougher work. He does not however, in his promises held forth to all alike who learn to draw, appear to realise the division of labour between the designer and the numerous mechanics who carry out the artist's ideas on the machine, but seems to look upon all artistic work as carried out single-handed from the design to the article ready for sale. No doubt it is here, as General Walker (already quoted) remarks, that there are boys that have genius in their eyes and fingers instead of a memory and quickness at book-training, who would profit by artistic training. Many such specially gifted artists have already made their mark in America both in architecture and in engraving; the standard of magazine illustrations having been raised even in England by competition with American productions. A larger class whose labour art-education makes valuable are women who are anxious to secure to themselves an independence. They are the principal teachers of drawing in all its branches, and find an excellent outlet for talent. Many artistic trades are also now carried on successfully by them; an account is especially given in Appendix E of the wood-carving taught at a women's school in Cincinnati introduced there by an English workman of the name of Fry. Ladies there, among others, make it a pursuit with great success.

Besides other papers incidentally referred to in our above remarks, various writings of considerable length and of dates from 1845 to 1884 are given in Appendixes A, C, and E, all urging the importance of art education, and instructing those engaged in teaching it.

Appendix F consists of 70 closely-printed pages giving an account of South Kensington, its officials, history, Art Training School, Museum, Art Library, art examples, books, and casts; with the reports for 1882 and 1884, and copious extracts from the Art Directory to show in detail the conditions and regulations under which "aid" is granted in England. Some of the quotations in this appendix are taken from the Directory of 1885. Mr. Clarke assures his countrymen that "in its appointments, and influence on art industrial education, South Kensington Museum stands without a rival. It is a wonderful centre of educational energy." "Other countries, even France, are giving it their official indorsement by modifying their art industrial instruction as rapidly as may be, and bringing it more into harmony with that of the English."

The final Appendix, H, claims to be a fitting end to this volume, and a foreshadowing of the contents of the future volumes. It is Lord Reay's address to the International Educational Conference at the Health Exhibition in 1884.

The printing of this volume is far from so correct as might be expected in a Government publication on Education. W. ODELL

OUR BOOK SHELF

American Journal of Mathematics. Vol. IX. No. 1. (Baltimore, October 1886.)

WE are glad to note that the successive parts now appear with praiseworthy regularity, and the arrival of our number can be predicted to a very close order of approximation. The volume opens with a continuation of Prof. Sylvester's lectures at Oxford on "The Theory of Reciprocants." The story is resumed with the eleventh and proceeds to the close of the sixteenth lecture. For the cumbrous terminology "projective reciprocants" or "differential invariants" the lecturer now suggests "principiants." From Lecture xiv. the abstract is devoted to the theory of pure and projective reciprocants, or rather principiants, and here we are introduced to the existence and properties of the protomorphs of invariants and reciprocants with which Mr. L. J. Rogers, one of the lecturer's audience, has made us elsewhere familiar. For an account of Dr. Story's new method in analytic geometry, we refer our readers to the author's own description. Dr. F. N Cole gives a full review in Klein's Ikosaeder of what that eminent mathematician has done in his "Vorlesungen über das Ikosaeder und die Auflösung der Gleichungen vom fünften Grade" (1884), and in his "Vergleichende Betrachtungen über neuere geometrische Forschungen" (1872). In Prof. Greenhill's paper on wave-motion in hydrodynamics the writer states that "one of the most important applications of the theory of hydrodynamics is to the question of the motion of waves under gravity and other causes," and his object is "to collect together the chief results hitherto obtained, and to give also a general connected account of the mathematical theory, at the same time attempting to develop it in some directions."

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Longitudes in Brazil

LE numéro du 18 novembre de NATURE publie un article du professeur Young sur les progrès de l'astronomie depuis dix ans, dans lequel il est dit que les observations de longitude télégraphiques des officiers américains ont corrigé une erreur de 8·54s. sur Lisbonne, et une bien plus étonnante encore de 35s. sur Rio.

Il y a là une grosse erreur inexplicable de la part du professeur Young, contre laquelle je dois protester comme auteur des cartes hydrographiques du Brésil encore employés aujourd'hui, et auteur de toutes les déterminations géographiques relatives et absolues faites douze ou quinze ans avant la mission américaine de MM. Green et Davis pour les longitudes télégraphiques entre le Brésil et l'Europe.

Sur les mille lieues de côte du Brésil la mission américaine a déterminé six longitudes entre le Para et Buenos Ayres. Voici la comparaison des résultats obtenus par MM. Davis et Green, à l'aide du télégraphe, et par moi, à l'aide de chronomètres et d'observations astronomiques directes. Les observations américaines sont publiées dans le numéro 59 (1880, je crois) "Hydrographic Notice," et les miennes dans les "Annales hydrographiques, 1866."

	Para h. m. s.	Pernambouco h. m. s.	Bahia h. m. s.
Long. télégraphique.	3 23 20·94	2 28 48·6	2 43 29·6
Long. Mouchez ...	3 23 18·67	2 28 47·5	2 43 26·9
Erreur	– 2·27s.	– 1·1s.	– 2·7s.

	Rio h. m. s.	Montevideo h. m. s.	Buenos Ayres h. m. s.
Long. télégraphique.	3 2 2·3	3 54 9·9	4 2 49·9
Long. Mouchez ...	3 2 0·1	3 54 9·4	4 2 49·9
Erreur	– 2·2s.	– 0·5s.	0·0s.

Il résulte de ce tableau que la plus grande erreur que j'ai commise est – 2·7s. sur Bahia. A Rio l'erreur est de – 2·2s., et non de 35s. comme le prétend M. Young. Dans le Rio de la Plata l'erreur a été trouvée nulle.

Je ne crois pas qu'aucune étendue de côte de mille lieues eut jamais présenté moins d'erreur absolue ou relative que la côte du Brésil après la publication de mes cartes et de mes observations.

Quant à l'erreur sur Lisbonne je l'avais signalée depuis plus de trente ans, elle était connue.

Je vous serais très obligé de vouloir bien publier au moins le tableau comparatif des longitudes que j'ai l'honneur de vous envoyer aujourd'hui, pour protester contre l'erreur qui m'est indirectement imputée.

Veuillez agréer l'assurance de ma parfaite considération.

E. MOUCHEZ

Cooke's "Chemical Physics"

I AM told that I have been the object of severe strictures in your journal for republishing my old "Chemical Physics" as if it were a new book. It is a sufficient answer to say that the book was stereotyped when first issued in 1860, and that there has never been any pretence on my part that it has been revised since. I find, on inquiry, that the American publishers have made, since the first edition, three reprints from the plates, and have called these reprints second, third, and fourth editions, changing, with each issue, the date on the title-page; a usage which I regard myself as reprehensible, but which must be sanctioned by the trade since it is so universally followed. All this time, however, the date accompanying my signature after the preface, and the date of the copyright, have remained unaltered. I had supposed the book entirely out of print; and the last reprint of a very few copies to meet a small demand still existing, chiefly in England, was made entirely without my knowledge or consent. On its very face the whole aspect of the book is antiquated; but in it there was brought together certain positive knowledge in connection with the weighing and measuring of aëriform matter, derived chiefly from the classical researches of Regnault, which is still of great importance and not readily found elsewhere; and this is, unquestionably, the reason of the continued demand for a compilation made more than twenty-five years ago. I have, until within a few years, had the expectation of revising the book and presenting the old facts in their new dress, but the failure of my sight has obliged me to give up the plan, and younger men must do the work.

Note on Mr. Budden's Proof that only One Parallel can be drawn from a Given Point to a Given Straight Line

MR. BUDDEN's paper in the last number of NATURE (p. 92) is full of inaccuracies of a more or less serious character. Without pointing out these, I wish to show that the essential idea which underlies his reasoning is altogether wrong, as it is based on the "infinite," which he introduces in the most innocent manner by letting his figure grow without limit, and about which he then calmly reasons as if he still dealt with a finite figure. If we let a quantity "increase without limit," we get a quantity which has increased beyond our comprehension, and no one in his senses will wittingly and seriously draw conclusions from what he does not comprehend. Here we might stop, were it not that the constant use in modern mathematics of the infinite (both the small and the great) has made us so familiar with it that an attempt to base an elementary proof on it might seem to many a very natural thing.

In algebra, the infinite number is shown to have one property which we can comprehend, viz. that its reciprocal is zero; and with this property alone we work safely.

In modern geometry, on the other hand, the infinite is used as a kind of shorthand, which enables us to make long statements short, and, at the same time, general. Taking the axiom about parallels for granted, it is shown that all points at an infinite distance in a line may be taken to be one point as far as constructions at a finite distance are concerned. For all lines joining a fixed point, P, to any point at infinity in a line may be taken as parallel to this line, and therefore as coincident. To express this more shortly, it is said that the whole indefinite and infinite part of a line which is out of the reach of our comprehension plays for us only the part of a single point, and accordingly it is called a "point," viz. *the point at infinity* of the line. Similarly it is shown that all points in a plane which are at an infinite distance may be considered as lying in one line, which is then spoken of as *the line at infinity* in the plane, and which is freely and safely used in deducing theorems and solving problems.

If, then, a line in a plane be moved to infinity, making always a given angle with a fixed line, it will ultimately become coincident with—which here means indistinguishable from—the line at infinity. The latter then makes with the fixed line a given angle. But this angle may be anything. Hence the "line at infinity" makes any angle we like with any given finite line; in other words, it makes no definite angle at all with it.

It follows, if we take a property of a figure which depends upon the magnitude of an angle, that this property will not necessarily any longer hold if one of the limits of the angle be moved to an infinite distance; for then this angle has not any longer a definite magnitude. To base any reasoning on that property after the figure has been indefinitely increased must therefore necessarily be fallacious. But this is exactly what Mr. Budden does. His proof is based on the implied assumption that if a figure in a plane be increased indefinitely, we can still reason upon it as if it were finite. He may take this as an *axiom*, but then he has *replaced* Euclid's axiom by another, and has not *proved* it; and the question would arise, Which form of the axiom is preferable? I prefer Euclid's.

O. HENRICI

Lunar Glaciation

I TRUST you will allow me a small space to explain regarding this theory of lunar glaciation, referred to by Mr. Darwin in NATURE (vol. xxxiv. p. 264).

First, I must thank him for the remarks made, and say that I certainly was not aware that Capt. Ericsson had been at work in the same direction some ten years or more before me.

I laid the theory before the late Prebendary Webb a few years ago, and some selections from it were published in the *Journal* of the Liverpool Astronomical Society, and, being necessarily incomplete, the extracts were not very intelligible. I have never attempted the settlement of the lunar surface temperature, which is quite beyond me, leaving the same in the hands of Prof. Langley, and have confined myself to the solution of the peculiar and unearthly surfacing we see. This I find best explained by glaciation, under conditions of intense cold, say $-60°$ or $80°$ C., and absence of all gaseous atmosphere.

I quite indorse Capt. Ericsson's conclusions as to the extreme unlikelihood of such a small globe being finally surfaced by igneous agencies, after it had seas of water, atmosphere, and probably *polar caps.*

Neison, in his "Moon," page 41, line 7, distinctly implies that this took place, *i.e.* "that this high temperature could only arise after the practical disappearance of bodies of water from the lunar surface," the rise in lunar temperature being due to solar heat.

I cannot follow Neison in this, and, on the contrary, believe that the temperature has steadily, if slowly, declined, from a period when there was erosion, with air and water. Polar caps then formed, as on our earth and Mars, and extended as the temperature fell, until at last the entire globe was cased in ice, the last portions to glaciate being what we call the equatorial seas.

Like Capt. Ericsson, I look on the craters and walled plains as having been lagoons of water, left here and there as glaciation extended, at places of greater depth, or more likely as submarine volcanic vents, for we see their sites as craterlets and cones after final glaciation.

The aqueous vapour given off from these lagoons would form a local dome-shaped atmosphere that would retard explosive ebullition, and on its reaching the outer limit of critical temperature, would condense and fall as snow; what fell beyond the lagoon margin would pile to form the ring, and the lagoon surface or flow be gradually lowered by its removal.

But I cannot follow Capt. Ericsson in supposing that the water had a centrifugal motion, and acted as a gigantic carving-tool, that sculptured the enormous terraces in Tycho, Theophilus, &c. On the contrary, I look on it as a quiet process, and that all the circular forms, from small craterlets to even such forms as Mare Crisium or Imbrium, with its huge maritime ranges, are due to one cause. The series is complete.

I quite agree with Mr. Darwin that a layer of water vapour would exist (and be visible) over the ice on the moon if only the temperature be high enough; but, at very low temperatures, ice practically does not vaporise even *in vacuo* (see Ganot's "Physics"). Aqueous vapour not being seen, I conclude the temperature is below (say) $-80°$ C. But the most potent argument in favour of my theory is that it reasonably and consistently explains *all* the peculiar features of lunar surfacing, *i.e.*:—

The absence of distinct Polar caps;
The absence of water and aqueous vapour (now);
The absence of distinct colour in details;
The brightness of all raised, rugged surfaces, mountains, cliffs, peaks;
The relative darkness of levels whereon meteoric dust can lie;
The extraordinary circularity of forms, large and small, incomplete, or overlapped;
The cones, whether central or isolated;
The clefts or rills, also strings of craterlets;
The maritime zones, ridges, and banks;
The haze or cloud, and nimbus or rayed brightness;
The dark points seen by Dr. Klein;
Lastly, if not least, the long bright rays.

I do not think I overstate the case when I say that selenographers will find these features consistently solved by the one hypothesis, and no enigmas left.

I cannot ask for space to go into details here, but will forward a short synopsis of the leading features, in case they may be required, arranging them as nearly as may be as in the preceding list.

Sibsagar, Assam, October 13

The Astronomical Theory of the Great Ice Age

THE lecture and the letter of Sir Robert Ball, however lucid, do not appear to carry this question further than where Dr. Croll left it. It is easy to understand that when the shape of the earth's orbit was different, winter days might be colder and summer days hotter than now. What the theory at present wants is an exposition of the successive series of effects by which this state of climates would transform the Emerald Isle into a mere Greenland. It is scarcely an explanation to say that "vast fluctuations like these must correspond to vast climatic changes of the kind postulated." We desire to be shown that they will correspond, and that the correspondence will be of the kind required. Taking Sir Robert Ball's own illustration, I am quite ready to admit that his horse alternately starved and crammed will not run a dead heat with one uniformly fed; but in default of experience I should not feel certain that his animal would die of accumulated fat.

We know that there have been past periods of heat-supply more uniform than at present, and periods of wider fluctuation. We see also in geological records ages of vast snow accumulation and ages of rich vegetation near the Pole. We need a demonstration that such wider fluctuations do tend to the one and not to the other; towards snow-accumulation and not towards snow-dissipation. Attempts in this direction have been made, but much seems needed yet.

St. John's College, Cambridge, November 23

Meteor

THE large meteor described in NATURE by Mr. P. L. Sclater, was observed here as follows:—

Nov. 17, 7h. 18m.—Fireball many times brighter than Venus. Path from $32\frac{1}{2}° + 45°$ to $158° + 55°$. Motion very slow, duration 7 seconds. Train, but no enduring streak. The fireball, as it gradually descended to the northern horizon, varied greatly in brilliancy, and gave a series of flashes lighting up the sky with great effect. I have occasionally seen larger fireballs, but never observed one more satisfactorily. This meteor was observed at Handsworth, Birmingham; at Crawshaw Booth, Lancashire; and at many other parts of the country. Its unusual brightness seems to have attracted wide notice.

Fireballs from Taurus are often seen at about this epoch; but that of November 17 appears to have belonged to a radiant-point in Aries.

Freshwater Diatoms in the Bagshot Beds

WILL you kindly favour me with space to ask any of your numerous readers, who may be specially interested, if they can furnish me with any references to published records of freshwater Diatoms being observed in the carbonaceous earthy sands of the Middle and Lower Bagshot Beds of the London Basin? In conjunction with one of my pupils, I have lately subjected many of these green and dark-grey sands and earths to microscopic examination; and our labours have been rewarded by the discovery of a rather extensive unicellular flora, particulars of which will be shortly laid before the Geological Society. Meanwhile, I shall be happy to have the co-operation of other workers in the same field.
A. IRVING

Wellington College, Berks, November 28

THE MATHEMATICAL TRIPOS[1]

I.

IT is with the greatest pleasure that I avail myself this evening of the already well-established custom which permits one of our members, once in two years, to address to his colleagues a few general remarks connected with the science that forms our common bond of union. It is not often that a mathematician has an opportunity of laying before his fellow-workers, by word of mouth, any views of his except such as relate to the actual mathematical investigations upon which he is engaged, which, from their very nature, can appeal directly only to the few who have laboured in the same field; and I feel it to be a high privilege to be permitted, in this room, and surrounded by familiar faces, to give expression to my thoughts and hopes upon subjects that are of common interest to us all as mathematicians.

[1] Address delivered before the London Mathematical Society by the President, Mr. J. W. L. Glaisher, M.A., F.R.S., on vacating the chair November 11, 1886.

I have not ventured to attempt any remarks upon the wide region of pure mathematics, or even upon the progress of such portions of it as have attracted the greatest share of interest among ourselves. I have felt that, as one who has resided and lectured in Cambridge for the past fifteen years, the most appropriate subjects for my address would be those upon which my residence in the University during an eventful period, or my experience as a lecturer, might to some extent qualify me to speak. Still, even when so restricted, I have found it no easy matter to decide upon the subjects to which I was most desirous of drawing your attention to-night.

I should like to have spoken at length upon the theory of elliptic functions. For fourteen years I have lectured regularly, each year, upon this subject, and no lectures of mine have been of so much interest to me. I believe that the time is rapidly approaching when the elementary portions of the theory will be regarded as necessarily forming part of the common course of reading of all students of mathematics, so that a familiarity with sn's, cn's, dn's, and their properties will become as essential as the differential calculus to the mathematical equipment of every person who has made mathematics one of his subjects of study.

Quite apart from its far-reaching influence in all branches of pure mathematics and its widespread applications in mathematical physics, there are special reasons which make the theory of elliptic functions a subject of peculiar interest in a course of mathematical studies, and one to which it is important that the student should be introduced as early as possible in his career, whether he be reading mathematics for its own sake, or for the sake of its applications, or for its advantages as a mental training. It is the first mathematical "theory" that he meets with in his reading—meaning by a "theory" a body of theorems and properties of functions so related to each other that the student cannot fail to see from the equations themselves that they form a consistent and remarkable system of facts, worthy of study on their own account, irrespective of any applications of which they may be susceptible. It is true that trigonometry, if regarded as the theory of singly periodic functions, is a theory in this sense, but it is reached by the student at too early a stage for him to be enabled to appreciate the nature and importance of facts that are expressed in the mathematical language of formulæ, and even if it were not so, the manner in which the subject is treated in text-books (the functions being derived from the circle and applied to the solution of triangles, &c., before they are considered analytically) makes it difficult to separate the mathematical theory from its various applications. In analytical geometry, which the student next meets with in his reading, a method of representing curves by equations is explained, and applied to the investigation and proof of properties of conics. In his next subject, differential calculus, he is introduced to new conceptions and processes of the very highest importance and the most fundamental character, and is taught to apply them to the investigation of maxima and minima, tangents and asymptotes to curves, envelopes, &c. Then come the elements of the integral calculus and of differential equations: the former consisting of a few chapters giving methods of integrating various classes of functions, followed by applications to curves and surfaces; and the latter of rules and methods for treating such equations as admit of finite solution.

Not one of these subjects, in the form in which they are necessarily presented to students, is an end in itself or exists for itself: they consist of ideas, methods, processes, and rules, which the student is taught to apply and to understand; they contain the conceptions with which he has to make himself as familiar as with the commonest facts of life, the tools which he is to have ever ready to his hand for use. And in the course of acquiring this knowledge he is made acquainted with numerous connected series of propositions—such as the properties of conics—besides various important results of more purely analytical interest. But all of these developments are presented to him in a form which throws no light upon the manner in which they were originally discovered, and, though the propositions are made to follow one another in clear logical order, the student cannot but be sensible that he is travelling, not along a natural highway, but upon a well-worn road, artificially constructed for his convenience. It is not till he reaches the subject of elliptic functions that he has the opportunity of seeing how, by means of the principles and processes that he has learned, a theory can be developed in which one result leads on of itself to another, in which every system of formulæ suggests ideas and inquiries about which the mind is eager to satisfy itself, and opens to the view fresh formulæ connected by unsuspected relations with others already obtained, so that he cannot resist the feeling that the subject is taking its own course, and that he is merely a bewildered spectator, delighted with the results which unfold themselves before him. He feels that the formulæ are, as it were, developing the subject of themselves, and that his part is passive: it is for him to follow where the formulæ point the way, and be amazed by the new wonders to which they lead him.

It may be that in using this language I am expressing the feelings of a mathematician, rather than those of a student on reading the elements of the subject for the first time; still I am convinced that the attributes I have just referred to are those which distinguish a genuine mathematical theory from a mere collection of useful principles and facts, and that no one can have studied elliptic functions without realising that mathematics is not only a weapon of research but a real living language—a language that can reveal wonderful and mysterious worlds of truths, of which, without its help, the mind could have gained not the least conception. It seems to me, therefore, of the highest importance that the student should be introduced to a real mathematical theory at the earliest stage at which his knowledge will permit of his deriving from it the peculiar advantages which I have mentioned. Thus only can he obtain expanded views or a true understanding of the science he is studying. Higher algebra and theory of numbers afford other conspicuous examples of the perfection that a pure mathematical theory can exhibit, but they do not lie so directly in the line of a general mathematical course of studies. Regarded from this latter point of view, elliptic functions has the additional merit of being a subject whose importance is recognised, on account of its physical applications, even by those to whom the gift of duly appreciating the wonders of pure mathematics seems to have been partially denied.

I should have liked also to have spoken at some length upon another subject that is constantly in my thoughts: I mean the pressing need of text-books upon the higher branches of mathematics. Of text-books for use in schools we have an abundance, and each month produces a fresh supply; but it is only occasionally that we have to welcome a work intended for the use of the higher University student or the mathematician. Every one of us must sometimes have felt the want of an introductory treatise that would give the reader the fundamental propositions in some branch of mathematics which exists only in memoirs and papers scattered throughout the wilderness of *Journals* and *Transactions* of Societies. We can scarcely expect to have provided for us, in many high subjects, text-books so admirable and thorough as Dr. Salmons; still I cannot refrain from expressing the hope that in the future the number of advanced mathematical treatises may not be so infinitesimal compared with the number of memoirs as at present. I could mention several subjects that are almost at a standstill, because advance is impracticable for want of avenues by which new workers can approach them. Of necessity the literature of mathematics must always be in the main a journal literature, for the audience addressed is small; but I cannot help feeling that the disproportion between the amount of exploration effected and the attempts made to render accessible the territories explored and conquered might be greater than it is. No one can realise more vividly than I do how vastly more difficult it is to write a book than a collection of memoirs, and how beset with anxieties, for any one who is at all fastidious, is the task of arranging the fundamental properties of any comparatively new subject in clear and logical form. The sustained struggle to attain clearness, exactitude, and thoroughness in the orderly development of a complicated and mutually-connected system of propositions wears out the worker more than thrice the same amount of labour devoted to new investigations with all the fascinating excitement of successes and failures, rewards and disappointments. In writing a memoir, the mathematician begins where he pleases, and confines himself to what has interested him and what he knows he has done well. In composing a book, the author has not only to marshal into order an array of theorems of various kinds, assigning to each its due place and importance, but he has—hardest task of all, perhaps—to confine his treatise within bounds, to keep it from growing to gigantic proportions as his increased study of the subject opens up to him fresh vistas. On the other hand, however, is to be considered the great service he can thus render to his favourite study: an introductory treatise on a subject not otherwise approachable by any direct route, even if it be not of the highest class, may have done far more for its advance than could have been effected by the most brilliant memoir. Time, care, and thought are essential for the preparation of any valuable treatise, and full references to the original memoirs should be always given; if these conditions have been fulfilled, the writer has deserved well of mathematical science.

I have not been able to forbear from making the few preceding remarks upon two subjects on which I have long felt strongly; but I pass now without further delay to the main subject of my address—the Mathematical Tripos. I have thought that, in view of the importance of this examination to our science, and the frequent changes that have taken place recently, this might be a subject of no ordinary interest to our members as well as to myself. Since 1872 change has succeeded change with great rapidity, and there are probably not many outside the mathematical portion of the resident body at Cambridge who are fully aware of the present mode of conducting the examination or of the further changes already sanctioned by the Senate and which take effect next June. It is, indeed, generally known that the list of wranglers, senior optimes, and junior optimes is published in June, at about the same time as many other Tripos lists, instead of by itself in January, and that the senior wrangler is displaced from his throne, and no longer owes his position to the results of the whole examination, so that he is not necessarily—even from an examination standpoint—the first mathematician of his year. So much only is generally known; and it has seemed to me that it might be of interest, considering the influence for good that it is hoped the examination in its new form will have upon the progress of mathematics, to give some account of the successive developments that have taken place in this time-honoured examination, and the causes and efforts that have led to them. The difficulties connected with the placing of all the mathematical candidates of the year in one order of merit, the extension or limitation of the subjects of examination, and various other questions connected with the Tripos, are matters that have been continually discussed and re-discussed in the light of fresh experience by those concerned with the mathematical course of studies at Cambridge, but I may, nevertheless, perhaps be permitted to-night very briefly to refer to some of the familiar arguments in the presence of a more extended audience of mathematicians.

It is convenient to preface the principal remarks I have to make by an outline of the history of the Tripos. In doing so, I must pass very lightly over its origin and early development, as anything approaching to a complete history of its origin and rise in the last century would amount almost to a history of the studies of the University.

At the beginning of the last century, besides certain merely formal disputations, the only exercises required from candidates for degrees were the keeping of acts and opponencies. Each candidate for honours in the course of his third year had to maintain publicly a thesis, the subject of which was chosen by himself, against three opponents, in the presence of one of the Moderators, who acted as umpire. The subjects selected were philosophical or mathematical; the discussion took place in Latin and in logical form. After hearing the discussions, the Proctors and Moderators prepared a final list of candidates qualified to receive degrees. This can scarcely be considered to have been an order of merit, for each of the Proctors and Moderators, and also the Vice-Chancellor, had the right to introduce the name of one candidate into the list whenever he pleased; still, except in the case of the recipients of these honorary degrees, it is probable that the list in the main fairly represented the merits of the candidates. It was divided into three classes, consisting of (1) the wranglers and senior optimes; (2) the senior optimes who had done fairly well but had not distinguished themselves; and (3) οἱ πολλοί, or the poll-men. The first class received their degrees on Ash Wednesday, taking seniority according to their order on the list, and the two other classes received their degrees later.

With regard to the origin of the Tripos, Mr. W. W. Rouse Ball, in his interesting sketch of its history,[1] writes:—

"The impressions gathered from these disputations in the schools were necessarily rather vague, and when they became the sole University exercise for a degree they hardly afforded a sufficient basis for an accurate arrangement of the men in order of merit. It was, I believe, to correct this fault that the Senate House examination was introduced, and I am inclined to think that it had its origin about the year 1730. At first it probably consisted only of a few *vivâ voce* questions addressed by the Proctors and Moderators in the week after the schools to those candidates about whose abilities and position some doubt was felt; but its advantages were so patent that within ten or twelve years it had become systematised into a regular examination to which all questionists were liable, although technically it was still regarded as only supplementary to the exercises in the schools. From the beginning it was conducted in English, and accurate lists were made of the order of merit of the candidates; two advantages to which, I think, its final and definite establishment must be largely attributed."

Mr. Ball divides the time during which the exercises in the schools and the Tripos were concurrent into five periods: (1) from 1730 to about 1750, during which time it was probably unauthorised and regarded as an experiment; (2) from 1750 to 1763, during which it was gradually establishing itself,—in the last year of this period it was officially decided that when a candidate's position in the class-list was doubtful the Senate House examination and not the disputation was to be taken as the final test; (3) from 1763 to 1779, during which definite rules were framed and laid down for conducting it; (4) from 1779 to 1827, during which it practically superseded the disputations; (5) from 1827 to 1841, the year in which the disputations were abolished.

The lists published in the Cambridge University Calendars begin with the year 1747, because in that year

[1] "The Origin and History of the Mathematical Tripos," Cambridge, 1880. (Reprinted from the *Cambridge Review*.)

the final lists were first printed and distributed, the names of those who had received honorary degrees being specially marked, so that by simply erasing them the true order of merit of the other candidates could be obtained. The division of the first class into wranglers and senior optimes was first made in 1753.

It was in the third of the above periods, that is, between 1763 and 1779, that the Senate House examination was gradually gaining ground upon the schools in determining a candidate's final place on the list. By means of their acts and opponencies the candidates were divided by the Moderators into eight classes, each class being arranged in alphabetical order; their subsequent position in the class was then determined by the Senate House examination. The first two classes comprised those who were expected to be wranglers, the next four included the other candidates for honours, and the last two consisted of poll-men only. The classes were examined separately and *vivâ voce.* During this period it became the custom to require written answers to the questions. The examiner gave out the questions to the class one by one, giving out a fresh question as soon as he saw that any one had finished the last. The problem papers, which were confined to the first two classes, were given to the candidates in writing, so that they had the whole paper before them at once.

It may be of interest to give a more detailed account of the exercises in the schools during this period, when both the exercises and the examination were in full operation and vigour. The Moderators, having received from the tutors of the Colleges a list of the students who were candidates for honours at the next examination, fixed a day in the Lent term on which each was to keep his act, and assigned to him three opponents. The Respondent, or "Act" as he was then called, selected three subjects which he proposed to maintain, and submitted them to the Moderator, who communicated them to his three opponents, designating them *opponentium primus*, *secundus*, or *tertius.* On the day fixed for the Act the respondent read his thesis in the schools in the presence of the Moderator. The first opponent then mounted the box opposite to that of the respondent and below that of the Moderator, and joined issue with him, opposing the thesis by eight arguments of syllogistic form. The respondent replied to each in turn, and when an argument had been disposed of, the Moderator called for the next in the words *Probes aliter.* When the disputation had continued long enough, the Moderator dismissed the opponent with such words as "*Bene disputasti*," or "*Optime disputasti*," or "*Optime quidem disputasti*," as the case might be. The second and third opponents (who had to oppose the thesis by five and three arguments respectively) entered the box successively, and after disputing were dismissed in the same manner, the whole performance lasting between one hour and two hours. The respondent himself was dismissed with some such phrase as "*Satis et optime quidem tuo officio functus es.*" Such compliments gave rise to the classification into senior and junior optimes. In general, "*Optime quidem*" was the highest praise expected even by future wranglers. The distinguished men of the year appeared eight times in the schools, twice as Respondents and twice in each grade of opponency.[1]

[1] Wordsworth, *Scholæ Academicæ* (1877), p. 37. A specimen of an argument, expressed in scholastic form, on the question, "Recte statuit Paleius de Virtute," is given by Wordsworth on p. 39, and the full system of eight arguments (in a disputation of 1784) on the question, "Solis parallaxis ope Veneris intra solem conspiciendæ a methodo Halleii recte determinari potest," is reproduced in detail by Mr. Ball in the appendix to the sketch already referred to. In the latter part of the last century it seems to have been usual for two of the questions to relate to mathematics and the third to moral philosophy. Wordsworth mentions that in 1710-11 it needed all the influence of an enthusiastic Proctor and Moderator to induce a student to keep his act in mathematical questions, but that by the middle of the century the examination was so far crystallising into the *Mathematical* Tripos that a questionist was enabled by academical authority in 1750 to resist the demands of a Moderator to produce one metaphysical question, he having already distinguished himself in mathematical argument. In the early Cambridge University Calendars the three questions given as specimens are: (1) "Recte statuit Newtonus in septima sua sectione Libri primi"; (2) "Iridis primariæ et secundariæ Phenomena solvi possunt ex Principiis Opticis"; (3) "Recte statuit Lockius de Qualitatibus Corporum."

The final establishment of the Mathematical Tripos dates, as remarked by Mr. Ball, from 1779. By the regulations agreed to by the Senate in that year, the Moderators of the previous year were added to the regular staff of examiners, and the system of brackets was introduced. The examination lasted three days (the last of which was devoted to moral philosophy), and on the fourth day a class-list, called "the Brackets," was issued, in which those candidates who were nearly equal were bracketed together. One day was devoted to the "examination of the brackets," by the result of which the names in each bracket were placed in order of merit. There was also a power of challenging, by which a candidate who was dissatisfied with his bracket might challenge any other candidate he pleased to a fresh examination;[1] but it seldom happened that any one rose above or fell below his bracket. From 1779 onwards the examination slowly and surely grew in importance, and the exercises became of less account each year, till they were finally discontinued by the Moderators in 1839. Two years later they were formally abolished by the Senate.

The following account of the Senate House examination in 1802 is abridged from the Cambridge University Calendar of that year:—"On the Monday morning, a little before eight o'clock, the students, generally about a hundred, enter the Senate House, preceded by a Master of Arts, who on this occasion is styled the father of the College to which he belongs. On two pillars at the entrance of the Senate House are hung the Classes [*i.e.* the eight classes into which the candidates have been divided by the exercises in the schools; and a paper denoting the hours of examination of those who are thought most competent to contend for Honours.

"Immediately after the University clock has struck eight, the names are called over, and the absentees being marked, are subject to certain fines. The classes to be examined are called out, and proceed to their appointed tables, where they find pens, ink, and paper provided in great abundance. In this manner, with the utmost order and regularity, two-thirds of the young men are set to work within less than five minutes after the clock has struck eight. There are three chief tables, at which six examiners preside. At the first, the senior Moderator of the present year and the junior Moderator of the preceding year. At the second, the junior Moderator of the present and the senior Moderator of the preceding year. At the third, two Moderators of the year previous to the two last, or two examiners appointed by the Senate. The two first tables are chiefly allotted to the six first classes; the third or largest to the οἱ πολλοί." After describing the manner of reading out the questions, the account proceeds:—"The examiners are not seated, but keep moving round the tables, both to judge how matters proceed and to deliver their questions at proper intervals. The examination, which embraces arithmetic, algebra, fluxions, the doctrine of infinitesimals and increments, geometry, trigonometry, mechanics, hydrostatics, optics, and astronomy, in all their various gradations, is varied according to circumstances: no one can anticipate a question, for in the course of five minutes he may be dragged from Euclid to Newton, from the humble arithmetic of Bonnycastle to the abstruse analytics of Waring. While this examination is proceeding at the three tables between the hours of eight and nine, printed problems are delivered to each person of the first and second classes; these he takes with him to any window he pleases, where there are pens, ink, and paper prepared for his operations." At nine o'clock the papers had to be given up, and half an hour was allowed for breakfast. At 9.30 all returned and were examined in the same way till eleven, when the Senate House was again cleared. An interval of two hours then took place. At

[1] In such cases the Moderators called to their assistance the Proctors or other Masters of Arts. About 1770 any Master of Arts was at liberty to examine any of the candidates. Mr. Ball is of opinion that this right was not insisted on after 1785.

one o'clock all returned again and were examined. At three o'clock the Senate House was again cleared for half an hour, and on the return of the candidates the examination was continued till five o'clock. This ended the Senate House examination for the day, but at seven in the evening the first four classes went to the senior Moderator's rooms to solve problems. They were finally dismissed for the day at nine, after eight hours of examination.[1] The work on the next day (Tuesday) was similar to that of the Monday; Wednesday was devoted to logic, moral philosophy, &c. "On Thursday the examinations are resumed, and continued nearly as usual, as on the Monday and Tuesday. At eight o'clock the new classifications, or brackets, which are arranged according to the order of merit, each containing the names of the candidates placed alphabetically, are hung upon the pillars." Fresh editions and revisions of the brackets were published at 9 and 11 a.m. and at 3 and 5 p.m., according to the course of the examination, liberty being given to any man to challenge the bracket immediately above his own. At five the whole examination ended. The Proctors, Moderators, and examiners then retired to a room under the public library to prepare the list of Honours, which was sometimes settled without much difficulty in a few hours, but sometimes not before two or three the next morning. The name of the senior wrangler was generally published at midnight. In 1802 there were eighty-six candidates for honours, and they were divided into fifteen brackets, the first and second brackets containing each one name only, and the third bracket four names.

The examination seems to have been a time of great excitement, and the list was most anxiously awaited. This was the case also before 1779, as appears from the account of the contest between Paley and Frere for the senior wranglership in 1763 and Jebb's account of the examination in 1772.[2]

Various changes took place in the examination in 1808, 1828, 1833, and 1839. In 1808 another day was added: three days were devoted to mathematics, exclusive of the day of examination of the brackets. Each candidate was employed eighteen hours in the course of the three days, of which eleven were devoted to book-work and the remaining seven to problems. By regulations which were confirmed by the Senate on November 13, 1827, and came into operation in January 1828, another day was added, so that the examination extended over four days, exclusive of the day of examining the brackets; the number of hours of examination was twenty-three, the time assigned to problems being the same as in 1808. On the first two days all the candidates had the same questions proposed to them, inclusive of the evening problems, and the examination on those days excluded the higher and more difficult parts of mathematics, in order, in the words of the report, "that the candidates for Honours may not be induced to pursue the more abstruse and profound mathematics to the neglect of more elementary knowledge." Accordingly, only such questions as could be solved without the aid of the differential calculus were set on the first day, and those set on the second day involved only its elementary applications. The classes were reduced to four, determined as before by the exercises in the schools. The regulations of 1827 are specially important, because they first prescribed that all the papers should be printed.[3] They are also noticeable as being the last which gave the examiners power to ask *vivâ voce* questions: after recommending that there be not contained in any paper more questions than well-prepared students have been generally found able to answer within the time allowed for the paper, the Report proceeds: "But if any candidate shall, before the end of the time, have answered all the questions in the paper, the examiners may at their discretion propose additional questions *vivâ voce*."

New regulations were confirmed by the Senate on April 6, 1832, and took effect in 1833. The commencement of the examination was placed a day earlier, the duration was five days, and the hours of examination on each day were five and a half. Thus four and a half hours were added to the whole time of examination, four of which were assigned to book-work and the remaining half-hour to problems. The examination on the first day was confined to subjects that did not require the differential calculus, and on the second and third days only the simple applications of the calculus were included. During the first four days of the examination the papers were set to all the candidates alike, but on the fifth day the examination was conducted according to classes. No reference is made to *vivâ voce* questions, and the examination of the brackets only survives in the permissive form: "That the result of the examination be published in the Senate House on the morning of the Friday succeeding the first Monday in Lent term, at nine o'clock; but if it should happen that the relative merits of any of the candidates are not then determined to the satisfaction of the Moderators and Examiners, that such candidates be re-examined on that day."

Only six years later these regulations were superseded by a new system, which passed the Senate on June 2, 1838, and came into operation in January 1839. By these new regulations another day was added to the examination, which thus lasted six days. The total number of hours of examination was thirty-three, of which eight and a half were given to problems. Throughout the whole examination the same papers were set to all the candidates. The regulations contain no mention of classes, and accordingly the exercises in the schools were discontinued by the Moderators. The permissive rule relating to the re-examination of the candidates (the survival from the brackets) was retained in these regulations in the same form as in those of 1832.

It is very interesting to notice, in the successive regulations, how the *vivâ voce* examination gradually merged into an examination by printed papers, and how, as the examination became more elaborate and exacting, it rendered unnecessary, not only the preliminary exercises in the schools, but also the final examination of the brackets.

Besides the development of the Senate House examination itself, other changes had taken place in the University system during this period of renewed activity. In 1824 the first Classical Tripos examination took place; only those who had already passed the mathematical examination being admissible as candidates. The name "Mathematical Tripos"[1] dates from after this year.

[1] In 1818 the hours for the evening problem paper were 6-10, so that the candidates had ten hours' examination in the day. Originally, as mentioned above, the problems were only set to the first two classes; in 1802 they were open to four classes, and in 1818 to all six classes, *i.e.* to all the candidates for Honours.

[2] Wordsworth (pp. 47 *et seq.*). See also the letters of Gooch, who was second wrangler in 1771 (p. 322).

3 The words of the report are:—"It is further recommended that the questions from books, which have hitherto been proposed to the classes *vivâ voce*, should, for the future, be printed. And it is hoped that, as by this means the questions proposed in each year will be more generally known, the students may thus be better directed in their reading than they now are, and the mathematical studies of the University become more fixed and definite. An opportunity will also be afforded of ascertaining by an inspection of these papers that the examination embraces a due proportion of each of the ordinary subjects of mathematical study.

"As, however, in proposing this alteration, the intention of the Syndicate is to avoid making any change in the substance of the examination, it is recommended that the examiners be strictly enjoined to insert in these papers such questions only as are at present proposed *vivâ voce*; namely, propositions contained in the mathematical works commonly in use in the University, or simple examples and explanations of such propositions."

[1] There are few matters in the history of the University more curious and interesting than the manner in which the word *Tripos* came to be applied to the Senate House examination, and consequently also to the other final Honour examinations. It is natural to suppose that it is connected with the three classes into which the Honour list was divided, but there is no connection whatever. The history of the name may be given briefly as follows:—In the ceremonies which were performed on Ash Wednesday in the middle of the sixteenth century, at the admission of questionists to be Bachelors of Arts, an important function was executed by a certain "ould bachilour," who was appointed as champion on the side of the University. He had to "sit upon

Previously it had been known as the Senate House Examination, and this name continued long afterwards and for more than thirty years was still printed as a heading to the papers set. It was only as a means of distinguishing it from the Classical and other newer Triposes that the name Mathematical Tripos gradually came into use. By the regulations which took effect in 1828 a totally distinct series of papers were set to the poll-men, who then formed the fifth and sixth classes. The fiction of regarding the poll-list as a continuation of the list of mathematical honours still lingered till 1858, the names being arranged in order of merit in four classes called the fourth, fifth, sixth, and seventh; the fourth class being in theory supposed to be the next class to that of the junior optimes.

(*To be continued.*)

THE COLOURS OF METALS AND ALLOYS[1]

THIS lecture is published by request, but the author fears that, dealing as it does with the colours of metals, such interest as it may have possessed when delivered will be greatly diminished in the absence of the experiments and diagrams by which it was illustrated.

I begin with no ordinary pleasure the work which has been intrusted to me by the Council of the British Association. It is nearly twenty years since this series of lectures was established. The first, on "Matter and Force," was delivered at Dundee by a brilliant experimenter and one of the most eloquent living exponents of science; it was followed, at Norwich, by a lecture by Prof. Huxley, to whom the nation owes a deep debt of gratitude for his intense sympathy with all who are seeking to widen the bounds of scientific knowledge—to be whose colleague in one of the most important scientific schools of the country is my great good fortune. These lecturers were succeeded by other eminent men, among whom may be mentioned Spottiswoode, Bramwell, and Lubbock. The object of the lectures is to diffuse a knowledge of the operations of Nature, and to add to the number of those who rejoice in her works. Many, therefore, who have spoken to audiences similar to this, have appealed to natural phenomena; and instead of talking to you about the colour of metals, I also should have liked to dwell on the colour of the sea and sky, but Ruskin's works are, I know, often in your hands, and he has told you once for all of the colour of clouds that "there is not a moment of any day of our lives when Nature is not producing scene after scene, picture after picture, glory after glory, and working still upon such exquisite and constant principles of the most perfect beauty that it is quite certain it is all done for us, and intended for our perpetual pleasure."[1] The metallurgist, however, cannot speak with authority on themes such as these; and I have therefore selected a subject which will, I believe, enable me to bring before you important truths affecting a wide range of industrial operations, and at the same time to sustain the true function of art by pointing to the direction in which we may have increased pleasure in things that constitute our most ordinary possessions, and which we use in daily life. First permit me to explain that I intend to include under the title of the lecture any facts which are, in my opinion, connected with the colours of metals and alloys, whether natural to them or produced by artifice, as well as a brief examination of the influence which the colours of metals appear to have exerted on the history of science.

I propose to begin at what will appear to be a somewhat remote starting-point. We say that copper is red, gold yellow, and silver white, but it is by no means certain that the early races of the world had any very clear perception of the difference between these several metallic colours. With regard to early Hebrew and Greek civilisation, Mr. Gladstone has expressed his belief that the colour-sense—that is the power of recognising colour and distinguishing it from mere brightness or darkness—was imperfectly developed, and he considers that "the starting-point is absolute blindness to colour in the primitive man," and he urges that the sense of colour has been gradually developed "until it has now become a familiar and unquestioned part of our inheritance." He adds: "Perhaps one of the most significant relics of the older state of things is to be found in the preference (known to the manufacturing world) of the uncivilised nations for strong and, what is called in the spontaneous poetry of trading phrases, loud colour."[2]

Dr. Magnus holds the view that the colour-sense in man has undergone a great improvement within the last 2000 years, and Prof. Haeckel supports this speculation, but it is opposed by Romanes, who has favoured me with some observations on the subject, in view of this lecture; and it seems to me strange, if savage nations are really deficient in the sense of colour, that the use of such colours as they can get in metals and fabrics, blended, for instance, in a war-club or a pipe-stem, should be so thoroughly "understood" and so discriminatingly employed as we sometimes find them to be. It may further be observed that primitive man may even have derived from his more remote ancestry some power of being influenced by colour, and we are told that the attraction which gorgeous colouring in flowers has for birds and insects, and which colour generally possesses for our nearer ancestors, has been of great importance in the origin of species, and in the maintenance of organic life.

No doubt, in ancient times, there was much confusion between mere brightness and colour, such as is evident in the beautiful sentence in which St. Augustine[3] says: "For this *queen of colours, the light*, bathing all which we behold, wherever I am through the day, gliding by me in varied forms, soothes me when engaged on other things and not observing her." If, however, it were proved that the power of distinguishing the colour of metals was not widely diffused among the Egyptians, Hebrews, and Greeks, it is at least certain that there were individuals of these nations to whom, in very early times, the colour of metals was all-important; and although they may have confused different precious stones under generic names, they certainly appreciated their various colours, and knew, moreover, that by fusing sand with the addition of a small quantity of certain minerals, they could produce artificial gems of varied tints.

a stoole before Mr. Proctours" and to dispute with the "eldest son" (the foremost of the questionists), and afterwards with "the father" (a graduate of the College to which the "eldest son" belonged, representing the paternal character of the College). At this time the only "Tripos" was the three-legged stool on which the Bachelor sat. A century later this Bachelor seems to have become a sort of licensed buffoon, and to have been called "Mr. Tripos," just as a president is sometimes referred to as "the Chair," or a judge as "the Bench." During the 120 years in which the name Tripos or Tripus indicated a personage there are frequent allusions to the humorous orations delivered in the schools by those who filled this office. These were known as Tripos speeches. It is probable that Mr. Tripos ceased to take part in the arguments in the schools between 1730 and 1750, just about the time when the Senate House examination was originating. The Tripos speeches were then replaced by copies of Latin verses, which were circulated on the admission days. These were called Tripos verses. About 1747 the Moderators began the custom of printing Honour lists on the back of the Tripos verses. Thus the list of Honours in the Senate House examination came to be called the Tripos list, so that a man's name was said to stand in such a place in the Tripos of his year, *i.e.* upon the back of the Tripos verses. And, lastly, the name was transferred from the list to the examination, the results of which were published in the list. This account is abridged from Wordsworth's *Scholæ Academicæ*, chap. ii. Wordsworth concludes: "Thus, step by step, we have traced the word *Tripos*, passing in signification, Proteus-like, from a thing of wood (*olim truncus*) to a man, from a man to a speech, from a speech to two sets of verses, from verses to a sheet of coarse foolscap paper, from a paper to a list of names, and from a list of names to a system of examination."

My object in leading you so far back—in discussing what appears to be a very matter-of-fact subject—is to point to the close connection between the early recognition and appreciation of colour in metals or minerals, and the foundation of the science of chemistry.

In early scientific history the seven metals known to the ancients were supposed to be specially connected with the seven principal planets whose names they originally bore, and whose colours were reflected in the metals; thus gold resembled the sun, silver the moon, while copper borrowed its red tint from the ruddy planet Mars. The belief in the intimate relation between colours and metals, the occult nature of which they shared, was very persistent, and we find a seventeenth-century writer, Sir John Pettus, saying[1] that "painters" derive "their best and most proper colours from metals whereof seven are accounted the chief, produced from the seven chief metals, which are influenced by the seven planets." A survival of this feeling is suggested by a modern writer, Leslie, who supposed that "when Newton attempted to reckon up the rays of light decomposed by the prism, and ventured to assign to them the famous number seven, he was apparently influenced by some lurking disposition towards mysticism."[2]

It would be impossible for me to overrate the importance of the colour of metals in relation to scientific history, for the attempt to produce a metal with the colour and properties of gold involved the most intense devotion to arduous research sustained by feverish, hope, attended by self-deception and elaborate fraud, such as hardly any other object of human desire has developed. It led to despair, to madness, and to death; but finally, through all, alchemy prepared the way for the birth of chemistry, and for the true advancement of science.

In early times, as now, gold was an extremely desirable form of portable property, and its colour was, perhaps, held to be the most distinctive and remarkable fact about it. I may incidentally observe that the dominant idea of colour in connection with the metallic currency survives in the familiar phrase, "I should like to see the *colour* of his money," which curiously expresses a desire, tempered by doubt as to its fulfilment. On looking back, we find that, at least from the third to the seventeenth century, the colour of gold haunted the early experimenters, and induced them to make the strangest sacrifices, even of life itself, in the attempt to imitate, and even actually to produce, the precious metal. Let us see what kind of facts were known within the period I have indicated. In barbaric times, hammered pieces of gold, or gold beaten into thin sheets and plates, were used with coloured stones and coral for personal adornment. The next step was to make gold go further by gilding base metals with it, and, in order to do this, the colour was for the moment sacrificed by combining the gold with quicksilver. This was done at least in the time of Vitruvius, B.C. 80, heat being used to drive away, as vapour, the quicksilver which had been united to the gold, leaving a thin film of precious metal on the surface to be gilded. But this was possibly not the first method of gilding, for we now know, from a papyrus of about the third century[3] of our era, that lead was used for this purpose. Gold, when fused with lead, entirely loses its golden colour, and yet, by the application of heat in air, the lead may be made to flow away as a fusible oxide, leaving the precious metal on the metallic object to be gilt, the base metal being as it were transmuted, superficially at least, into gold. The point I want to insist upon is that the metallic colour of the gold vanished during the process as carried on by the craftsman, only to re-appear at the end of the operation; and I am satisfied that it was from such simple technical work as this that the early chemists were led to think that the actual production of gold—the transformation of base metals into gold—was possible. The more observant of them, from Geber, the great Arabian chemist of the seventh century, to our own countryman, Roger Bacon, in the thirteenth, saw how minute a quantity of certain substances would destroy the red colour of copper, or the yellow colour of gold. A trace of arsenic will cause the red colour of copper to disappear; therefore, the alchemists very generally argued, some small quantity of the right agent, if only they could find it, will turn a base metal to the colour of gold. Look, they said, how small a quantity of quicksilver will change the appearance of metallic tin. Here is a bar of tin 2 feet long and 1 inch thick, which it would be most difficult to break, though it will readily bend double. If only I rub a little quicksilver on its surface a remarkable effect will be produced, the fluid metal will penetrate the solid one,[1] and in a few seconds the bar will, as you see, break readily, the fractured surface being white, like silver. It was by such facts as this that men were led to believe that the white metal, silver, could be made.

Successive workers at different periods held divergent views as to the efficacy of the transmuting agent. Roger Bacon, in the thirteenth century, held that one part of the precious substance would suffice to turn a million parts of base metal into gold. Basil Valentine, in the fourteenth century, would have been content with the transmutation of seventy parts of base metal by one part of the agent. While, coming to the end of the eighteenth century, Dr. J. Price, F.R.S., of Guildford, only claimed that the substance he possessed would transmute from thirty to sixty parts of base metal.[2]

It is a curious fact that no one seems to have actually prepared the transmuting agent for himself, but to have received it in a mysterious way from "a stranger"; but I must not dwell on this. I will merely point out how persistent was the view as to the singular efficacy of the transmuting agent, and I will content myself with a reference to Robert Boyle, our great countryman, an accurate chemist of the seventeenth century, who did more than any one else to refute the errors of alchemy. He nevertheless characteristically records[3] the following experiment, in which, instead of ennobling a base metal, he apparently degraded gold to a base one. He first purified a small quantity of gold, about "two drachms," with great care, and, he states, "I put to it a small quantity of powder communicated to me by a stranger," —it is singular that even he should have received the transmuting agent in the usual way,—"and," he adds, "continuing the metal a quarter of an hour on the fire, that the powder might diffuse itself through it, . . . the metal when cold appeared to be a lump of *dirty colour;* . . . 'twas brittle, and, being worked with a hammer, it flew into several pieces. From hence," he adds, "it appears that an operation almost as strange as that called 'projection'" (or transmutation) "may safely be admitted, since this experiment shows that gold, . . . the least mutable of metals, may in a short time be exceedingly changed . . . by so small a portion of matter that the powder transmuted a thousand times its weight of gold." He elsewhere observes of a similar experiment, "transmutation is nevertheless real for not being gainful, and it is no small matter to remove the bounds which Nature seems very industriously to have set to the alterations of bodies."[4] The change in the

colour of the gold was remarkable, but Boyle had only produced one of the series of alloys most dreaded by every jeweller—"brittle gold"—for the way in which an alloy of gold and copper is affected by a small quantity of impurity presents one of the most serious difficulties in working gold. It has been known since the seventh century, that minute quantities of certain metals render gold brittle, and it may be well to demonstrate the fact.

Here are two hundred sovereigns: I will melt them and will add in the form of a tiny shot a minute portion of lead amounting to only the 2000th part of the mass, first, however, pouring a little of the gold into a small ingot, which we can bend and flatten, thus proving to you that it is perfectly soft, ductile, and workable. The rest of the mass we will pour into a bar, and now that it is sufficiently cold to handle, you see that I am able to break it with my fingers, or at least with a light tap of a hammer. The *colour* of the gold is quite altered, and has become orange-brown, and experiments have shown that the tenacity of the metal, that is, the resistance of the gold to being pulled asunder, has been reduced from 18 tons per square inch to only 5 tons. These essential changes in the property of the metal have been produced by the addition of a minute quantity of lead. I have cited these facts mainly to show that the changes produced in the colour and properties of metals by small variations of composition were such as to lead the alchemists on in their belief that it was possible to change lead or tin into gold, and the hope in which they worked enabled them to gather facts out of which chemical science was gradually constructed. We shall see presently that changes in the colour of metals and alloys produced by the addition of small quantities of foreign matter, are of great importance in the application of metals to artistic purposes, but we must first try to examine more closely some of the prominent facts connected with the colour of metals, that is, the effect metals have on light so as to produce the effect of colour in our eyes. We are apt to think of gold as being essentially and distinctively golden-yellow; it may, however, possess a wide range of colours without in any way losing the condition of absolute metallic purity, its relations to light depending entirely on the nature of its surface, and especially on whether the metal is in mass or in a more or less fine state of division. Interesting as gold is to us in mass (and I may incidentally mention that during my official connection with the Mint I have been responsible for the quality of 462 tons of it) it is perhaps still more interesting to us when beaten so fine that a single grain, of the value of 2*d*., would cover a space of 48 square inches, or when it is so finely divided that the dimensions of a single particle may closely approximate to those of the ultimate atom.

This aspect of the question was investigated by Faraday, and the experimental part of the subject remains practically unadded to since his time. It is well known that a leaf of gold when seen by transmitted light is either green or blue, according to its thickness. Here is such a leaf of green gold, as seen when light is actually sent through it (Fig. 1), so as to project a green disk on the screen. A portion of the light will be *reflected* from its surface, and this reflected ray may be caught in a mirror and thrown on the screen so that you have, shown side by side, the green disk of transmitted light and the golden one of reflected light from the same leaf of gold.

Gold may readily be converted into a soluble chloride which produces a beautiful golden solution. If such a solution contains very little gold, not more than 2 grains in a gallon, and if certain chemical methods be adopted to precipitate the gold, that is, to throw it out of solution in a *solid*, though in a very fine state of division, the metal may exhibit a wide range of tint, from ruby to black.

[A few drops of phosphorus dissolved in bisulphide of carbon had been added to about a gallon of a very dilute solution of chloride of gold contained in a tall glass cylinder, as shown in the sketch (Fig. 2). The beam from an electric light, thrown through the vessel, revealed in the lower part the presence of finely-divided metal of the natural golden colour, while the more finely-divided gold in suspension imparted a brilliant ruby colour to the liquid, and a glowing ruby disk was projected on a white screen.]

When gold is in the "ruby" state, it is so finely divided that each particle probably approximates to the dimensions of the gold atom.

[The solar spectrum was then thrown upon the screen, and the audience was invited to compare it with a diagram which, while closely resembling the solar spectrum,

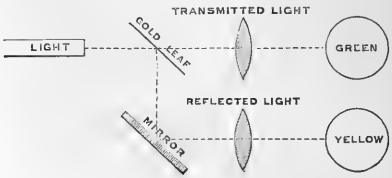

FIG. 1.

really represented the way in which pure metallic gold, prepared by various methods, is capable of behaving in relation to light so as to produce the sensation of a wide range of colours.]

It would be easy to show that light is similarly affected by other metals; but I have selected gold for the purpose of illustration because it is easy to maintain it in a state of purity, however finely divided it may be. We must therefore modify any views we may have formed as to a metal having exclusively a special colour of its own, because it

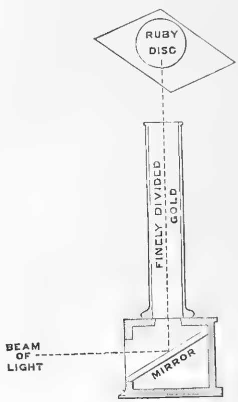

FIG. 2.

will be evident that a particular colour is only due to a definite state of arrangement of its particles. The intimate relation between the state of the surface of a metal and its colour is well shown by the beautiful buttons devised by Sir John Barton. He proved that if very fine lines be drawn close together, so that about 2000 would be ruled in the space of an inch, a beautiful iridescent effect is produced, the tints being quite independent of the metal itself due to an optical effect of the lines.

[The image of such a button was then thrown upon the screen.]

Let us now examine some effects of uniting metals by fusing them together into what are called alloys; and, second, the direct influence of a minute quantity of one metal in changing the mass of another in which it is hidden, and causing it to behave in a different way in relation to light, and consequently to possess a colour different from that which is natural to it; or the added metal may so change the chemical nature of the metallic mass that varied effects of colour may be produced by the chemical combinations which result from the action of certain "pickling" solutions. This portion of the subject is so large that I can only hope to set before you certain prominent facts.[1]

First, with reference to the colour produced by the union of metals. Here is a mass of red copper, and here one of gray antimony: the union of the two by fusion produces a beautiful violet alloy when the proportions are so arranged that there is 51 per cent. of copper and 49 per cent. of antimony in the mixture. This alloy was well known to the early chemists, but unfortunately it is brittle and difficult to work, so that its beautiful colour can hardly be utilised in art. The addition of a small quantity of tin to copper hardens it, and converts it, from a physical and mechanical point of view, into a different metal. The addition of zinc and a certain amount of lead to tin and copper confers upon the mettal copper the property of receiving, when exposed to the atmosphere, varying shades of deep velvety brown, characteristic of the bronze which has from remote antiquity been used for artistic purposes. But by far the most interesting copper alloys, from the point of view of colour, are those produced by its union with zinc, namely brass. Their preparation demands much care in the selection of the materials, and I might have borrowed from the manufacture of brass instance after instance of the influence of traces of impurity in affecting the properties of the alloy, but it is unnecessary to dwell upon this alloy in Birmingham, for in all that relates to the mechanical manipulation of the alloys of copper with tin and with zinc, you are masters. I have many inducements in this place to speak about this beautiful alloy. I am proud to be a namesake of the craftsman, William Austen, who, in 1460, made that magnificent monument in brass which covers the remains and commemorates the greatness of Richard Beauchamp, Earl of Warwick, and I am glad to remember that Queen Elizabeth granted the first patent for the manufacture of brass in England to William Humfrey, Assay Master of the Mint, a predecessor in the office it is my privilege to hold.

I want, however, to direct your attention to-night to some alloys of copper with which you are probably less familiar than with brass. In this direction Japanese art affords a richer source of information than any other. Of the very varied series of alloys the Japanese employ for art metal-work, the following may be considered to be the most important and typical. The first is called "shaku-dō"; it contains, as you will observe from Analyses I. and II.,[2] in

Shaku-dō.

I.		II.	
Copper	94·50	Copper	95·77
Silver	1·55	Silver	0·08
Gold	3·73	Gold	4·16
Lead	·11		
Iron and Arsenic	traces		
	99·89		100·01

addition to about 95 per cent. of copper, as much as 4 per cent. of gold. It has been used for very large works. Colossal statues are made of it; one cast at Nara in the seventh century being specially remarkable. The quantity of gold is, however, very variable; specimens I have analysed contained only 1·5 per cent. of the precious metal. The next alloy to which I would direct your attention is called "shibu-ichi." There are numerous

Shibu-ichi.

III.		IV.	
Copper	67·31	Copper	51·10
Silver	32·07	Silver	48·93
Gold	traces	Gold	·12
Iron	·52		
	99·90		100·15

varieties of it, but in both these alloys, shaku-dō and shibu-ichi, the point of interest is that the precious metals are, as it were, sacrificed in order to produce definite results; gold and silver, when used pure, being employed very sparingly to heighten the general effect. In the case of the shaku-dō, we shall see presently the gold appears to enable the metal to receive a beautiful rich purple coat or *patina*, as it is called, when treated with certain pickling solutions; while shibu-ichi possesses a peculiar silver-gray tint of its own, which, under ordinary atmospheric influences, becomes very beautiful, and to which the Japanese artists are very partial. These are the principal alloys, but there are several varieties of them, as well as combinations of shaku-dō and shibu-ichi in various proportions, as, for instance, in the case of kiu-shibu-ichi, the composition of which would correspond to one part o shaku-dō rich in gold, and two parts of shibu-ichi rich in silver. Interesting effects are produced by pouring two alloys of different tints together just at the solidifying point of the less fusible of the two, so that the alloys unite but do not blend, and a mottled surface is the result. These alloys are introduced into almost every good piece of metal-work.

Now as to the action of pickling solutions. Many of you will be familiar with the mysteries of the treatment of brass by "dipping" and "dead dipping," so as to produce certain definite surfaces, but the Japanese art metal-workers are far ahead of their European brothers in the use of such solutions.

The South Kensington Museum contains a very valuable series of fifty-seven oblong plates, some plain and others richly ornamented, which were specially prepared as samples of the various metals and alloys used by the Japanese. The Geological Museum in Jermyn Street has a smaller, but very instructive, series, of twenty-four plates presented by an eminent metallurgist, the late M. Hochstätter-Godfrey. From descriptions accompanying the latter, and from information I have gathered from certain Japanese artificers now in London, it would appear that there are three solutions generally in use. They are made up respectively in the following proportions, and are used boiling.

	I.	II.	III.
Verdigris	438 grains	87 grains	220 grains
Sulphate of copper	292 ,,	437 ,,	540 ,,
Nitre	—	87 ,,	—
Common salt	—	146 ,,	—
Sulphur	—	233 ,,	—
Water	1 gallon	—	1 gallon
Vinegar	—	1 gallon	5 fluid drachms

That most widely employed is No. I. When boiled in No. III. solution, pure copper will turn a brownish red; and shaku-do, which, you will remember, contains a little gold, becomes purple; and now you will be able to appreciate the effect of small quantities of metallic impurity as affecting the colour resulting from the action of the pickle. Copper containing a small quantity of antimony gives a shade very different from that resulting from the pickling of pure copper. But the copper produced in Japan is the result of smelting complex ores, and the

[1] A list of books and papers dealing with the colours of metals and alloys, and with the production of coloured patina, is given by Prof. Ledebur in his work "Die Metallverarbeitung," p. 285, 1882, published in Bolley's "Technologie."

[2] Analyses Nos. I. and III. are by Mr. Gowland, of the Imperial Japanese Mint at Osaka; Nos. II. and IV. by Prof. Kalischer, *Dingl. Polyt. Journ.*, ccxv. 93.

methods of purification are not so perfectly understood as in the West. The result is that the so-called "antimony" of the Japanese art metal-workers, which is present in the variety of copper called "kuromi," is really a complex mixture containing tin, cobalt, and many other metals, so that a metal-worker has an infinite series of materials at command with which to secure any particular shade; and these are used with much judgment, although the scientific reasons for the adoption of any particular sample may be hidden from him. It is strictly accurate to say that each particular shade of colour is the result of minute quantities of metallic impurity, and these specimens and diagrams will, I trust, make this clear, and will prove that the Japanese arrange true pictures in coloured metals and alloys.

[This portion of the subject was illustrated with much care by coloured diagrams representing specimens of Japanese art metal-work; by photographs projected on the screen, as well as by the reflected images of small ornaments made of the alloys which had been specially referred to. There was also a trophy of leaves of copper of varying degrees of purity coloured brilliantly by one or other of the "pickles" above described.]

There is one other art material to the production of which I hope art workmen in Birmingham will soon direct their attention, as its applications are endless. It is called in Japanese "mokume," which signifies "wood-grain." It is now very rare even in Japan, but formerly the best specimens appear to have been made in Nagoya by retainers of the Daimio of Owari. I have only seen six examples, and only possess a single specimen of native work, and have therefore had to prepare a few illustrations for you in soldered layers of gold, silver, shibu-ichi, shaku-dō, and kuromi.

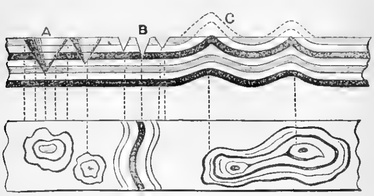

Fig. 3.

This diagram (Fig. 3) shows the method of manufacture. Take thin sheets of almost any of the alloys I have mentioned, and solder[1] them together layer upon layer, care being taken that the metals which will present diversity of colour come together. Then drill conical holes of varying depth, A, in the mass, or devices in trench-like cuts of V section, B, and hammer the mass until the holes disappear; the holes will thus be replaced by banded circles and the trenches by banded lines. A Japanese artificer taught me to produce similar effects by taking the soldered layers of the alloy, and by the aid of blunted tools making depressions on the back of the mass so as to produce prominences on the front, C. These prominences are filed down until the sheet is again flat; the banded alloys will then appear on the surface in complicated sections, and a very remarkable effect is produced, especially when the colours of the alloys are developed by suitable "pickles." In this way any device may be produced. In principle the method is the same as that which produces the *damascening* of a sword-blade or gun-barrel, and depends on the fact that under certain conditions metals behave like viscous solids, and as truly "*flow*" as pitch or honey does, only in the case of mokume the art workman has a wide range of tinted metals at command.

Throughout Japanese art metal-work, in which I hope you will take increasing interest, there is the one principle of extreme simplicity and absolute fidelity to nature. The brilliant metals, gold and silver, are used most sparingly, only for enrichment, and to heighten the general effect; these precious metals are never allowed to assert themselves unduly, and are only employed where their presence will serve some definite end in relation to the design as a whole. A Japanese proverb asserts that "He who works in gold puts his brains into the melting-pot," meaning, I suppose, that this metal, so precious from an artistic point of view, demands for its successful application the utmost effort of the workman, and suggesting that gold should not be employed in massive forms such as would result from melting and casting, but should be daintily handled, beaten on to the work, or embedded with the hammer.

Bear in mind that in Birmingham, when a really fine work is produced in silver, the surface is often made gray by chemical means, "oxidised," as it is termed, and this subordination of the brilliancy of silver to artistic effect, is well understood by the celebrated American firm, Messrs. Tiffany, of New York, who are doing so much to catch the spirit of Japanese art metal-work. All I ask you to do is to carry this still further—to cover base metals with these glowing coloured oxides, and thus to add to the permanence of art work, by producing surfaces which will resist the unfavourable atmospheric influences of our cities.

Hitherto we have considered the union of metals by fusion, but fire is not the only agent which can be employed for this purpose. Two or more metals may be deposited side by side by the aid of the electric battery. Birmingham was, as you well know, the early home of electro-metallurgy, an industry to the development of which the great firm of Elkington has so materially contributed. I have no statistics as to the amount of precious metals annually employed for electro-deposition in Birmingham, but it is known that a single works in Paris, belonging to M. Christofle, deposits annually six tons of silver, and it has been estimated that the layer of silver of the thickness actually deposited on various articles would, if spread out continuously, cover an area of 140 acres.[1] I will not, however, dwell upon the deposition of gold and silver in their normal colours. I would remind you that copper and zinc may be deposited by electrolysis so as to form brass, and that all the beautiful bronzes and alloys of the Japanese can be obtained by galvanic agency; and further, by suitable admixtures of gold, silver, and copper, red-gold, rose-coloured gold, or green gold may be deposited, so that the electro-metallurgist has at his command the varied palette of the decorative artist.

[The images of beautiful deposits of coloured gold, specially prepared by Messrs. Elkington, were then projected on the screen.]

I ought to allude to what has been called the moral aspect of colour, and although I cannot follow Goethe[2] in his attributes of colour, which seem to me to be fantastic and over-strained, I quite recognise the poetic sympathy of Shakespeare in making Bassanio select the casket of lead, which contained the warrant for his earthly happiness, because "its paleness moved him more than eloquence." I ask you to remember Ruskin's words, that "all men completely organised and justly tempered enjoy colour; it is meant for the perpetual comfort and delight of the human heart; it is richly bestowed on the highest works of creation, and the eminent sign and seal of perfection in them being associated with life in the

[1] The following solder was found to answer well:—

Silver	55·5
Zinc...	26·0
Copper	18·5
	100·0

[1] H. Bouilhet, *Ann. de Chim. et de Phys.* t. xxiv. p. 549, 1881.
[2] Farbenlehre.

human body, with light in the sky, with purity and hardness in the earth; death, night, and pollution of all kinds being colourless."

I must briefly turn to the concluding part of our subject. It has long been known that thin films of certain metals and certain metallic oxides act on light in the same way as thin films of other translucent substances. I have here such thin films of oxide of lead, which, many years ago, Nobili, Becquerel, and Gassiot taught us to deposit, and such films have since been used in decorative metal-work.

[Beautiful examples of such films were projected on the screen.]

I wish I had time to point to the great interest and importance of films of coloured oxide of iron in the tempering of steel, for it is well known that, apart from the scientific interest of the subject, the shades from straw-colour to blue which pass over the surface of hardened steel when it is heated in air, afford precious indications as to the degree of temper the metal has attained, and in no industry is this better shown than in the manufacture of steel pens. I must pass this over, and turn to one other instance of the formation of coloured films on metals. Here is an ordinary plumber's ladle filled with lead, which will soon be molten when it is placed over this flame. The air will play freely on the surface of the melted lead, and, as a certain temperature is reached, very beautiful films will pass over the surface of the metal. If the lead contains very minute quantities of cadmium or of antimony, the effect will be greatly heightened. If the light from the electric lamp be allowed to fall on the surface of the bath of lead, it will be easy to throw the image of the metallic surface on the screen, and you will see how beautiful the films are and how rapidly they succeed each other when the metal is skimmed. What, then, is the special significance of the experiment from our point of view? It represents in a singularly refined way the one experiment which stands out prominently in the whole history of chemistry; for the formation of a coloured scum on lead when heated in air has been appealed to, more thany any other fact, in support of particular sets of views from the time of Geber in the seventh century to that of Lavoisier in the eighteenth. It was the increase in weight of the lead when heated in air that so profoundly astonished the early chemists; and, finally, the formation of a coloured oxide by heating lead in air was the important step which led on your great townsman, Priestley,[1] to the discovery of oxygen; and, as the fact of his residence among you will never be forgotten, Birmingham may claim to have been connected, through him, with one of the most splendid contribution ever offered to Chemical Science.

[1] He pointed out that the experiment with minium confirmed his view that he mercury calcined in air derived oxygen *from* the air.

NOTES

PROF. RÜCKER, F.R.S., has been appointed by the Lord President of the Council to the Professorship of Physics in the Normal School of Science and Royal School of Mines, rendered vacant by the death of Prof. Guthrie, F.R.S.

AT the Royal Society on Thursday last (November 25) a paper was read by Sir Richard Owen, containing some further evidence on the structure of the very remarkable extinct marsupial, *Thylacoleo carnifex*. The author re-affirmed his previous statements that it was a carnivorous beast of the size of a lion, the probable prey of which had been the larger herbivorous marsupials, also now extinct. Prof. Flower, after reviewing the additional evidence that had been adduced, repeated his conviction expressed eighteen years ago in a paper read before the Geological Society, that the dentition of *Thylacoleo* found no parallel in any existing predaceous carnivore, but was formed on a totally different type, and that there was therefore no justification for assigning to it habits for which it did not seem particularly well adapted. The essential conditions in a dentition which would enable an animal to seize and overcome large and struggling prey, as seen in both lions, tigers, wolves, and the existing carnivorous marsupials, are large canines set well apart, with incisors so small as not to interfere with their piercing action; whereas in *Thylacoleo* the canines are rudimentary, and the central incisors greatly developed. The alternative, sometimes suggested, that the animal was herbivorous, was equally improbable. In fact, it would not be safe to do more than speculate on the habits or food of an animal the dentition of which was so highly specialised, and without any analogy in the existing state of things. Prof. Huxley said that he agreed with the conclusions of the last speaker.

A COURSE of six lectures, adapted to a juvenile auditory, on "The Chemistry of Light and Photography" (with experimental illustrations), will be given at the Royal Institution by Prof. Dewar, M.A., F.R.S., on the following days, at three o'clock:—Tuesday, December 28, 1886; Thursday, December 30; Saturday, January 1, 1887; Tuesday, January 4; Thursday, January 6; Saturday, January 8.

THE Royal Society have just received from Egypt a consignment of specimens of the different strata of soil in the Delta. The borings have been carried out to a depth of nearly 200 feet, and the solid bottom has not yet been reached. The Royal Engineers in Egypt have been intrusted with the work. The specimens, which are chiefly of sand and clay strata, are deemed of great importance, and the Society has granted money for the continuance of the work, which will be carried out by the detachment of Engineers as hitherto.

THE Secretary of State for War has given permission for Sir Frederick Abel, C.B., the Chemist of the War Department, to accept the post of organising secretary to the Imperial Institute, provided that the duties do not interfere with those of his appointment under the War Office; and Sir Frederick Abel has been desired by the Prince of Wales, President of the Imperial Institute, to enter upon his work as soon as possible. The new secretary has just completed his work in connection with the electric lighting of the Indian and Colonial Exhibition, and is also retiring from his duties in connection with the Society of Arts.

ON November 17, at 7h. 18m. p.m., a fine fireball was seen at Stonyhurst College, Blackburn. It appeared to be several times as bright as Venus. In colour it was violet, and of a distinct pear shape. The part of its path observed, as far as could be judged from the stars seen through detached clouds, was from near ι Ceti to the small stars above Fomalhaut, about 88 Aquarii. Its path was slightly curved. So brightly did it shine that attention was first called to it by the illumination of the sky, although seen from a room in which the gas was lighted.

THE *Morning Star* of Jaffna, in Ceylon, reports the death of the taxidermist of the Victoria Museum in that town from the bite of a cobra, under very curious circumstances. While feeding a cobra, which he had supposed was harmless from previous extraction of the poison-bag, it suddenly bit his hand. For a few minutes he took no notice, thinking the bite harmless, but pain and nausea soon began. Carbolic acid was applied, ligatures were bound round the arm, an incision was made at the bite, and the blood of the arm was wholly removed. Various antidotes were used, but the unfortunate man lost the power of speech, and soon after every muscle seemed to have become paralysed, and breathing entirely ceased.

Artificial respiration was therefore resorted to, and this operation was unceasingly continued for nine hours, when at last the patient made an attempt to breathe, and soon regained consciousness enough to make his wants known. He steadily improved until the Friday, the accident having taken place on a Wednesday, and then astonished those around him by stating that during the severe operation of Wednesday night he was conscious of all that was taking place, but was unable to make his feelings known, not having power over a single muscle. It would seem that the poison paralysed the nerves of motion, but not those of feeling, for he could see, and hear, and feel, although the physicians, even by touching the eyeball, could get no response either of feeling or consciousness. His partial recovery was, however, followed by a high fever and inflammation of the lungs, and he died, perfectly conscious, on the following Sunday.

THE New Zealand Government are about to collect salmon ova in Scotland and transfer them to that colony for incubation. It will be remembered that the Royal Commissioner for New Zealand has previously carried out similar work successfully, and it has been found that the *S. salar* thrives well in the waters of that possession. Last year a large number of salmon ova were collected from Scotland, and hatched out and reared in New Zealand.

COMMENCING on January 1, 1887, a journal is to be published by the National Fish-Culture Association, comprising not only information regarding its transactions from time to time, but also articles relative to the subjects of fish-culture, fish, and fisheries. A record will also be given of what takes place in connection with these subjects throughout the whole of the United Kingdom, the colonies, and abroad.

A STRONG shock of earthquake, lasting several seconds, was felt at Smyrna and in the adjacent districts early on the morning of November 27, and news has been received of Tchesme and Chios having been similarly visited. A strong shock was felt at Tashkend on the morning of November 29, causing damage to many houses in the Russian quarter. Two shocks were felt on Sunday at Somerville and at Charleston. A slight shock was felt in Cairo at half-past four o'clock on the afternoon of the 17th. The vibration lasted several seconds.

DURING the past summer, Dr. Fr. Svenonius, the well-known Swedish geologist, has been prosecuting geological, ethnographical, and glacial studies in Swedish Lapland.

ON the evening of November 4 a splendid display of the aurora borealis was seen at Throndhjem, in Norway. Not only the northern, but also the eastern and part of the southern, sky were covered with aurora. The radiation was particularly brilliant from south-west to north-east, forming a wreath in all the colours of the rainbow. During October, several splendid displays of aurora occurred, but none as brilliant as this one.

ON the evening of October 30 a brilliant meteor was seen from the Faloterbo lightship, on the south-west coast of Sweden. It went in a direction south-south-west to north-north-east, exploding, as it seemed, from time to time, and displaying the most brilliant yellow, red, and green light. At times the sky was illuminated as in full moonlight. About a couple of minutes after the last explosion, reports as of guns were heard. At about 2 a.m. of November 5 another splendid meteor was seen at Hamar, in Norway. It went in a southerly direction across Lake Mjösen, and disappeared from view, leaving a long, broad, variegated trail behind.

PROF. COLLETT, the well-known Norwegian zoologist, announces that the beaver is now extinct in Northern Norway, but estimates that about 100 are still in existence in the south, chiefly in the province of Nedenaes.

A KITCHEN-MIDDEN has just been discovered at Ginnerup, in Denmark, at the foot of a cliff near a dried-up sound. It is about a yard in depth and of considerable extent, and contains quantities of shells of oysters, mussels, &c.

THE last numbers of the *Journal* of the China Branch of the Royal Asiatic Society (vol. xxi. Nos. 1 and 2) contain a "Symposium" on the question whether Western knowledge, and especially, of course, Western science, should be conveyed to the Chinese through the medium of their own or of a Western language. Fourteen of the leading European scholars in China took part in the discussion. Their views will not bear classification under the heads affirmative or negative, as some hold a middle place, exhibiting a leaning in one direction or another. The general tendency, however, is in favour of exciting the curiosity and interest of intelligent Chinese in the matter of Western knowledge by popular exposition in the native tongue, while reserving a more adequate representation for a time when a sufficient number of Chinese shall have acquired foreign languages to constitute a learned class in our sense of the expression. A further and final stage will be reached when the members of this class, themselves impregnated with foreign knowledge, shall convey it to their fellow-countrymen in their own tongue, gradually modified to suit the exigencies of doctrines now absolutely foreign to the genius of the Chinese language and beyond its capabilities.

IN the course of the discussion, some interesting facts with regard to the translation of scientific terminology into Chinese were mentioned. Dr. Martin, of Pekin, referred to Ricci's old translation of Euclid, which he entitled "The Fundamental Principle of the Science of Quantity." Oxygen, hydrogen, and nitrogen are translated so as to express their characteristics of supporting life, of lightness, and of derivation from nitre. On the other hand, Dr. Macgowan mentions that a translator's difficulties in dealing with natural history terms are really enormous. He undertook the translation of Dana's "Mineralogy" and Lyell's "Elements of Geology" into Chinese for the Government, and a scientific native scholar was detailed to assist him. When they came to the plants that have the names of foreign botanists, most of them polysyllabic, they were appalled, and as they could only be rendered phonetically, the native scholar decided against translating any portion of the plant's name, transferring it bodily, according to sound, into Chinese. Similarly, the complex nomenclature of organic chemistry presents a formidable difficulty. A Chinese clergyman, who took part in the discussion, delivered a particularly interesting address, urging that the phonetic method should, as a rule, be employed, on the ground that the characters used in the translation of scientific terms have traditional meanings to the Chinese mind, and thus great confusion is created. The "term"-controversy which has agitated theologians in China for the past half-century, and has divided them into two hostile camps, appears likely to revive in the domain of science, the question lying between translation or phonetic reproduction.

FROM a study of thirty-two years' observations of thunderstorms in the Vienna region, Dr. Hann finds that there is a double maximum of frequency. The greatest number occur in the first half of June, the second smaller maximum is in the end of July; between these is a secondary minimum. (Thunderstorms hardly ever occur in winter.) This agrees with observations in Munich. In Brussels most thunderstorms occur in the second halves of June and July. The daily period in Vienna shows a chief maximum about 3.20 p.m., and a secondary one at 1.2 a.m. The spring and summer storms come mostly from the east or south-east, and seem to belong to Mediterranean depressions, coming up from the Adriatic, as those of late summer seem to be on the south or south-east border of Atlantic depressions.

BETHNAL GREEN FREE LIBRARY has been doing a large amount of good work in the thickly-populated district in which it is situated, not only by giving facilities for reading books, but by science lectures and science "talks." It is much in want of funds for the extension of operations, and we commend it to the consideration of our readers. The librarian is G. F. Hilcken.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus*) from India, presented by Miss G. M. Fisher; a —— Hedgehog (*Erinaceus* ——) from Madras, presented by Mr. H. R. P. Carter; two Mute Swans (*Cygnus olor*), European, a Common Peafowl (*Pavo cristatus*) from India, presented by Lady Siemens; a Red and Yellow Macaw (*Ara chloroptera*) from South America, presented by Mr. Arthur Daunt; a Grey Parrot (*Psittacus erithacus*) from West Africa, presented by Mrs. Greenwood; five Great Eagle Owls (*Bubo maximus*), European, presented by Mr. Philip Crowley, F.Z.S.; a Common Guillemot *Lomvia troile*), British Islands, presented by Mr. J. H. Gurney, F.Z.S.; two Gambel's Partridges (*Callipepla gambelli*) from California, presented by Mr. W. A. Conklin, C.M.Z.S.; a Malabar Green Bulbul (*Phyllornis aurifrons*) from India, received in exchange; five Great Titmice (*Parus major*), four Blue Titmice (*Parus cæruleus*), two Bullfinches (*Pyrrhula europæa*), European, purchased.

OUR ASTRONOMICAL COLUMN

THE ARGENTINE GENERAL CATALOGUE OF STARS.—This Catalogue, containing the mean positions of 32,448 southern stars determined at the National Observatory of Cordoba, has recently been published by Dr. Gould. The observations from which the Catalogue positions are deduced were made with the meridian-circle of the Cordoba Observatory during the years 1872–80. During these years the zone-observations were the chief object of attention, and the present Catalogue contains the places of those stars whose positions were more elaborately determined during the progress of that great work, and constitute an addition to our knowledge of southern stellar positions of perhaps not less importance than the Cordoba Zone-Catalogue. The General Catalogue gives the positions, for the epoch 1875·0, of most of the southern stars brighter than magnitude 8½, the deficiencies in this respect being chiefly found north of the parallel of 23°, at which the zones begin. These omissions will be of comparatively small importance, inasmuch as the new *Durchmusterung* of Prof. Schönfeld comprises all the southern stars within this region, while accurate determinations of the brighter ones will have been made in the re-observation of Lalande's stars now nearly completed at the Paris Observatory.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 DECEMBER 5–11

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on December 5

Sun rises, 7h. 51m.; souths, 11h. 50m. 51·4s.; sets, 15h. 50m.; decl. on meridian, 22° 25′ S.: Sidereal Time at Sunset, 20h. 47m.

Moon (two days after First Quarter) rises, 13h. 30m.; souths, 19h. 35m.; sets, 1h. 51m.*; decl. on meridian, 0° 19′ N.

Planet	Rises	Souths	Sets	Decl. on meridian

THE ROYAL SOCIETY[1]

FOR many years it has been my duty as senior secretary to read at each anniversary the death-roll of the year. The names this year are perhaps slightly fewer than usual, but many recall to us faces once familiar that we shall never see here again. Earliest among them comes Sir Frederick Evans, whose death took place only very shortly after our last anniversary. In the course of the preceding summer he crossed the Atlantic to take part in that International Conference which assembled at Washington, to deliberate among other things on the choice of a common prime meridian for all civilised nations. On his return he was looking ill, and the illness increased until it carried him away. Yet even through his illness he kept on working at science, at a task he had undertaken, and which was almost completed when he died. To this I shall have occasion to refer again. In Mr. Busk we have lost one who has long been among us, and who took an active part in the scientific business of the Society. He repeatedly served on our Council, and both then and subsequently gave us the benefit of his extensive knowledge and sound judgment in the important but laborious task of advising the Committee of Papers as to the proper mode of dealing with papers which they referred to him. In Lord Cardwell we have lost a statesman whose political duties did not prevent him from coming among us and serving on our Council. The public services and singular honesty and straightforwardness of Mr. Forster are appreciated by the nation at large. Quite recently, at no advanced age, we have lost Prof. Guthrie, the occupant of a chair which a great many years ago I held for a time; a man whose genial character drew around him a close circle of friends. Still more recently we have lost the Earl of Enniskillen, whose fine palæontological collections are well known to geologists. Only the other day one passed away whom we seldom missed at our anniversary meeting, and who was frequently with us on other occasions: I allude to General Boileau, whose philanthropic labours will not soon be forgotten, and may, I trust, be recognised in a much needed form.

The Fellows will have noticed with satisfaction a very con-

[1] Anniversary Address by Prof. G. G. Stokes, President, on Tuesday, November 30, 1886.

siderable excess of income over expenditure in the balance sheet for the year. At first sight it might be supposed that as the *Transactions* come out at irregular intervals there might have been fewer parts published than usual; but it will be found on examination that the past year has borne its proper share of printing expenses. The excess is really due to a substantial improvement in the Society's property, under the careful and judicious management of our Treasurer.

Last year our President informed the Fellows of the munificent offer made to the Society by Sir William Armstrong to give to the Scientific Relief Fund the sum of 6500*l*., provided an equal sum were raised by subscription from the Fellows, and, if need be, other friends of science who might not belong to the Society. As the Fellows are aware, a circular was sent round by the Treasurer mentioning Sir William Armstrong's generous offer, and inviting subscriptions; and the Treasurer has also written privately to a number of persons, Fellows and others. The sum subscribed or promised in response to this invitation amounts to about 4200*l*.; and though the sum thus raised does not amount to what Sir William promised to duplicate if it could be raised, he has most generously not only waived the non-fulfilment of the condition subject to which the former offer was made, but has still further augmented it; and he now promises not only to duplicate the sum raised in answer to the Treasurer's appeal, but to give the further sum of 3600*l*., thus raising the capital from the present sum of about 8000*l*. to 20,000*l*. He will be ready to pay the whole sum of 7800*l*. as soon as the subscriptions promised to the Treasurer have been collected. The only condition attached to this princely gift is, that, besides meeting the ordinary objects for which the Fund was instituted, the Council should feel themselves at liberty to apply a portion of the income to defraying the annual subscriptions of Fellows in special cases where such a course might seem desirable.

The path of the total eclipse of September 9 of last year, in any place where it fell on land, was so remote from this country that no expedition went out to observe it. It was visible in New Zealand, and in anticipation of it our Eclipse Committee sent out a memorandum to the colony indicating the points of special interest to look out for. We have received accounts, drawings, and photographs of the eclipse from Dr. Hector and others. One of the most remarkable features of this particular eclipse was the appearance of two white and unusually bright prominences which attracted general notice, and were compared to electric lamps, and which, situated on opposite sides of the sun, were just over the places of two large spots, one close to the limb, and on the point of disappearing, the other not seen before the eclipse but visible next day, having in the meantime come round the limb.

The present year afforded another of those rather rare occasions, always of brief duration, which are afforded for the study of solar physics by a total eclipse of the sun. Calculations made long beforehand showed that a total eclipse was to be expected on August 29. The path of the total phase on the earth's surface is always narrow, say 100 miles or so across, and on this occasion it swept obliquely across the Atlantic Ocean, cutting the Western Coast of Africa about Benguela, and sweeping across some of the West India Islands to a part of the mainland of South America, where it ended.

Though there was a long belt of ocean over which the totality would be visible, and where the imposing spectacle of a total eclipse might be witnessed, this was not available for regular scientific observations, which require land on which to fix the instruments. On the mainland of America the total phase would come on so shortly after sunrise that the sun would be too low for good observations, and therefore the Island of Grenada, which lay within the belt of totality, was much to be preferred.

Of the two available stations, one lay in the British dominions, and was pretty easy of access from England, and accordingly it seemed to be the duty of our country to take a foremost place in the observations, the results of which would be available to the whole scientific world. It was contemplated first to send expeditions to both places—to Benguela as well as Grenada. The cost of this would, however, exceed what could be spared from the Government Grant without unduly curtailing what was available for other objects. Accordingly application was made to the Lords of the Treasury for a grant of 1000*l*. towards the cost of the expeditions. Inquiries were also made as to the probable climate at the two places; and here I have to express our thanks to the Governor-General of the Windward Islands, who put us in communication with Dr. Wells of Grenada, from whom we obtained valuable information regarding the climate of that island, and to the Consul-General for Portugal, who obtained information for us from the Polytechnic Institution at Lisbon as to the amount of sunshine about the end of August at Loanda, which may be taken pretty well as representing Benguela.

The information we obtained from various sources as to Benguela was rather conflicting, but there seemed a pretty general agreement that even if the sun should be shining at the time of the eclipse the sky was likely to be hazy. This would much interfere with good observations, especially as regards the corona; and as the expense of the expedition to Benguela would be considerable, and the success very doubtful, we thought it better to give up that part of the project and confine ourselves to Grenada. Being anxious to trench as little as possible on the national expenditure, and finding that a little more could be taken from the Government Grant than we had expected, we wrote to the Treasury reducing our application to 500*l*., which, with assistance from the Admiralty in the shape of the use of a ship-of-war on the West India station, and supplemented by some money from the Government Grant and from our own Donation Fund, might enable us to meet the expenditure.

The result was that a sum not exceeding 500*l*., to supplement what could be spared from the Government Grant, was granted, and the expedition, as the Fellows are aware, has sailed and returned. It was fairly successful, the observations having been prevented by clouds at only one of the stations occupied.

There has not yet been time to discuss the observations in full, but two points already appear to have come out pretty clearly. One is that the brightness of the corona, which on this occasion was actually measured, was much less than had been expected, and less apparently than it had been on former occasions. This seems to show that the brightness is liable to great changes in comparing different years, as we know is the case with the form. The other point touches on the question of the possibility of photographing the corona independently of an eclipse. If the photographic brightness of the corona be not overpowered by that of the atmospheric glare immediately around the sun when there is no eclipse, then when the sun is partially eclipsed we might expect to be able to trace the outline of the limb of the moon for some way outside the sun, since the moon would be projected on the background of the corona. The experiment was tried both by Capt. Darwin at Grenada, and by Dr. Gill at the Cape, but in neither case was the limb traceable outside the sun. This throws doubt on, but does not disprove, the validity of the method; for Dr. Huggins himself has never obtained photographic appearances apparently referable to the corona since the Krakatão eruption. It may be that the finely suspended particles, whether connected with the Krakatão eruption or not, which produced those gorgeous sunsets that were so remarkable, have not yet wholly subsided, and cause a considerably increased atmospheric glare. It may be that the corona has actually been much less bright than usual for the last few years.

The present year has been signalised by that remarkable volcanic explosion in New Zealand, of which we have read accounts in the newspapers. We have received from Dr. Hector a series of photographs of the district, taken at no great length of time after the explosion.

The Krakatão Committee, which was appointed at the suggestion of our late President to collect information relative to the great eruption, have now I may say completed their work. The Royal Meteorological Society had appointed a Committee to get together information respecting the remarkable atmospheric phenomena witnessed after the eruption. It was thought desirable that the two Committees should work in concert, and accordingly our Committee was enlarged by the addition of two members of the Royal Meteorological Society, even though they did not happen to be members of the Royal Society, who undertook that share of the work. The information collected under this head is naturally voluminous, since it requires no special training to describe the atmospheric appearances. Our late Fellow, Sir Frederick Evans, undertook the sea-disturbance, and continued to work at it even in an advanced stage of the disease which carried him off. Another fortnight, it was estimated, would have enabled him to complete it. His account was found to have been written in pencil on separate sheets of note-paper, but his successor in the office of Hydrographer, Captain Wharton, our Fellow, was so good as to take up the work; and partly by the use of materials left by Sir F. Evans, partly by his own independent labour, he has now completed it. The report on air-disturbance was undertaken by General Strachey, and is ready. Prof. Judd undertook geology; the materials are ready, and though the actual report is not yet written, the writing would take but very little time. Mr. Scott undertook to collect information as to floating pumice; but as it has been found that the Krakatão pumice does not possess distinctive features whereby it could be recognised, and therefore the origin of the pumice that ships have encountered at a distance from Krakatão remains unknown, little trustworthy information could be obtained under this head, and the report has been handed over to Prof. Judd to embody with the geology. The heaviest part of the report, that relating to sunsets and atmospheric phenomena, has been prepared by the Hon. Rollo Russell and Prof. Archibald, the two Fellows of the Royal Meteorological Society who have been mentioned as having been added to the Committee, and is ready, with the exception of a little revision, and it remains only to prepare an introduction, index, &c. The whole report may therefore be regarded as all but complete in manuscript, and it will be for the new Council to deal with it.

The Circumpolar Committee have now brought their labours to a close, the report on the observations taken by Capt. Dawson at Fort Rae being printed and published. The reports of the expeditions undertaken by Austria, the United States of America, Germany, and Holland are, I understand, complete, and those by France and Russia are in a forward state. Before the accounts of the observations taken at different stations by the observers of different nations shall have been for some time before the public, it would be premature to expect general conclusions to be deduced from this great undertaking.

Very satisfactory progress has been made during the past year with the publication of the Report of the *Challenger* Expedition. The volumes already published and in the Society's Library now amount to sixteen on Zoology, and three introductory on other subjects. Others are in a very forward state, and it is expected that the whole will be published very nearly within the time mentioned by the Committee, probably at the end of the next financial year.

As mentioned in the Presidential Address last year, advantage has been taken of the British occupation of Egypt to make some explorations by way of boring in the Delta of the Nile, to the results of which geologists attach great importance. The War Department has allowed some of the staff of the Royal Engineers, when their services were not otherwise required, to take part in the operations, and has lent the boring apparatus, and the Royal Society voted the sum of 350*l*. out of its own Donation Fund to defray the cost of labour and other incidental expenses. It was contemplated originally to make a chain of borings, but the depth to which it has been found necessary to proceed in order to get through the ordinary deposit has turned out to be so great that it was thought better, instead of attempting many, to try and get if possible down to rock, or to something else which might afford evidence that what could be referred to alluvium from the Nile or drifted sand had really been got through. A deep boring has accordingly been made at Zagazig, under the direction of Capt. Dickenson, R.E. This has now been carried to a depth of 190 feet 6 inches below the surface, or 164 feet 5 inches below the mean sea-level at Alexandria, and yet nothing has been reached but sand and clay with small pebbles. Prof. Judd is now engaged in the examination of the matter brought up. A derangement of the boring apparatus prevented for the present further progress, and the use of a narrower pipe than any at hand would be required for carrying the boring deeper. The Committee considered that it would be more important to extend this boring, so as if possible to get down to rock, or else to Miocene fossils, than to make a fresh boring in a different place, and arrangements are being made accordingly. The inquiry was deemed a proper one to be assisted out of the Government Grant, and the sum of 200*l*. has been voted from this source to supplement the Royal Society's grant already mentioned.

The ordinary meetings of the Society are well known, and are frequently attended by strangers by permission of the Fellows present; and the papers brought before us are known to the world through our publications. But a great deal of scientific work is done of which the outside public knows nothing. There have been thirteen meetings of the Council during the year, and the attendance at our council meetings is remarkably good. There have been more than seventy meetings of committees and sub-committees.

There is further another task on which a great deal of gratuitous and conscientious labour of the highest kind is bestowed. I allude to the examination of papers with a view to advising the Committee of Papers as to their publication. The past year has shown no flagging in scientific activity in relation to papers brought before us.

The preparation of the manuscript for another decade, 1874 to 1883, of the Royal Society's catalogue of scientific papers, is now almost complete. This great work has been extremely useful to men of science in enabling them at once to find where a memoir on a particular subject, written by an author whose name they know, as is usually the case, is to be found. To some extent it enables them also to find what has been written on a particular subject, for there are usually one or two authors, whose names they know, who have made it a special study, and on consulting their papers references are frequently found to the writings of others who have written on the same subject. Nevertheless, it must be confessed that the value of the catalogue would be greatly increased if it could be accompanied by a key, of the nature of an *index rerum*. It was originally contemplated that this should be added, but the magnitude of the undertaking has hitherto prevented the Committee from attempting it. To be well done it would require the long-continued labour of a scientific staff representing different branches of science, and they could not be expected to engage in so heavy a work without adequate remuneration.

A great deal of work has been done during the past year in relation to the library. More than 5000 volumes have been removed to other rooms to make space for the more important works constantly accruing. A list of duplicates and deficiencies has been printed and circulated among corresponding societies. A shelf catalogue is in progress, and is about a third of the way towards completion. Some work has also been done upon a catalogue of miscellaneous literature.

The electric lighting of the Society's apartments, which is now complete, seems to have given general satisfaction.

On August 31 of this year, our distinguished Foreign Member, M. Chevreul, attained his hundredth year. Rarely indeed is it given to any one to see right through a century, more rarely still to retain his powers to such an age, yet both, I am happy to say, have been granted to M. Chevreul. In anticipation of this event, preparations were made for its due celebration. I received an invitation for our Fellows to assist at the celebration; but unfortunately it was at a time of year when most of us were scattered, and moreover time did not permit of making it generally known. I am afraid we had no representative at the actual ceremonial, but I am sure that none the less our hearts were with the veteran *savant*.

This year has also witnessed the celebration of the 250th anniversary of the University of Heidelberg. The Council had appointed our Foreign Secretary as a deputation to represent the Society on the occasion. Unfortunately when the time was close at hand, Dr. Williamson was prevented by the condition of his health from taking part in the celebration; but acting on the emergency on behalf of the Society, I requested our Fellow, Sir Henry Roscoe, to take his place, which he was so good as to do.

In his Presidential Address last year, Prof. Huxley suggested the idea, I may say expressed the hope, that the Royal Society might associate itself in some special way with all English-speaking men of science; that it might recognise their work in other ways than those afforded by the rare opportunities of election to our foreign membership, or the award of those medals which are open to persons of all nationalities alike. This suggestion has been taken up in one of our colonies. We have received a letter from the Royal Society of Victoria, referring to this passage in the Address, and expressing a hope that in some way means might be found for establishing some kind of connection between our own oldest scientific Society and those of the colonies.

The Council have appointed a Committee to take this letter into consideration, and try if they could devise some suitable plan for carrying out the object sought. The Committee endeavoured at first to frame a scheme which should not be confined to the colonies and dependencies of the British Empire, but should embrace all English-speaking communities. But closely connected as we are with the United States by blood and language, they are of course politically a foreign nation, and this fact threw difficulties in the way of framing at once a more extended scheme, so that the Committee confined themselves to the colonies and dependencies of our own country, leaving the wider object for some future endeavour, should the country concerned seem to desire it. The scheme suggested was laid before the members of the present Council, but there was not an adequate opportunity of discussing it, and it will of course come before the new Council. Should they approve of some such measures as those recommended by the Committee, they will doubtless assure themselves in some way or other that those measures are in accordance with the wishes of the Fellows at large before they are incorporated into the Statutes.

But in connection with this subject there is another suggestion which I would venture to offer, and which I know has been thought of by others.

A good many years ago it was not unusual to elect to the Fellowship men of distinguished eminence in departments other than scientific. More recently a change was made in the Statutes whereby Privy Councillors are enabled to become Fellows by a special method, without interfering with the selection by the Council of fifteen from among the candidates whom they recommend to the Society for election. This to a certain extent superseded the necessity of appealing to other than scientific claims, and in some respects the method had special advantages. Those who attained to a place on Her Majesty's Privy Council were sure to be distinguished men, whom we should be glad to welcome among us; and by confining the privilege of special election to these, with whose appointment the Council had nothing to do, all invidious distinctions were prevented. But the method has the disadvantage that it applies only to a particular class of merit. A man, for instance, might be of quite first-rate eminence in poetry or literature, but that would not lead to a seat on the Privy Council. Such a man could only be elected by being placed on the selected list of fifteen. But it seems to me that there is something not quite courteous either to the eminent man himself, or to the scientific man who would have to be passed over to make room for him, in thus putting him in competition with those who seek admission on purely scientific grounds. I cannot help thinking that it might be well if the Council had the power of recommending for special election men of high distinction on other than scientific grounds, whose connection with us would on both sides be felt to be an honour, and who, though not, it may be, themselves scientific, might usefully assist us by their counsel. I do not think it would be difficult to devise means for providing that such a privilege should be accorded only in case of very high eminence.

The application of photography to the delineation of celestial objects has of late years made rapid strides; and, partly owing to the improved sensitiveness of the plates, partly to greater exactness in regulating the motions of equatorially-mounted telescopes, it has been found possible to photograph even minute stars. The question is accordingly now seriously entertained whether we may not trust to photography for the formation of star maps and star catalogues, taking eye-observations on a sufficient number of stars here and there for reference, and trusting to differential measurements taken on the plates for determining the positions of the other stars. Indeed, I think the practicability of this application may now be considered as established, and there only remains the question of the best mode of carrying it out on a uniform plan. In the course of the autumn I had a letter from Admiral Mouchez, Director of the Paris Observatory, in which he informed me that in response to the presentation of specimens of the admirable star photographs taken by the MM. Henry, several of the astronomers to whom they had been sent suggested that it would be well that a conference of astronomers of various nations should be held, with a view to taking concerted action for obtaining on a uniform plan a complete map of the whole starry heavens. He wished accordingly to obtain an expression of opinion on the part of the Royal Society as to the desirableness of holding such a conference; and as it was contemplated, in case the proposal should be favourably entertained by those consulted, that the conference should be held at Paris in the spring, and it would be necessary to give timely notice to the astronomers who live in the southern hemisphere, an early reply was requested.

As it would have defeated Admiral Mouchez's object to wait till the Council should re-assemble after the recess, I wrote at once to consult four of our Fellows specially named by Admiral Mouchez; and on receiving their replies I wrote to Admiral Mouchez, saying that under the circumstances I took it upon me to express in the name of the Royal Society our approval of the suggestion, explaining at the same time that I did so on the understanding, which I fully believed to be in accordance with his intention, that the astronomers who might attend the conference should not be considered as pledged to the adoption of the methods or scale of the MM. Henry, but that the whole subject should be open to discussion. On reporting what I had done to the Council when they met after the recess, I obtained an expression of their approval.

In these photographs a remarkable instance was exhibited of the power of photography to reveal the existence of objects wholly invisible to the eye. One of the stars of the Pleiades was found to be surrounded by a nebula which cannot be seen with telescopes. The reason of the difference of power of the plate and eye is very obvious: with the eye an object is either seen or not seen at once, whereas with the plate, provided there be an absence of stray light, feebleness of intensity can be made up for by length of exposure.

But the MM. Henry are by no means the only persons who have applied photography to the delineation of the stars. Among others, our Fellow, Dr. Gill, who has sent us some excellent specimens of the photographs obtained by his instrument, proposes to take at the Cape Observatory photographs of the whole starry heavens of the southern hemisphere, under such conditions as to include the magnitudes contained in Argelander's "Durchmusterung" of the northern hemisphere, and to subsequently reduce the observations so as to complete Argelander's great work by extending it to the southern hemisphere. Prof. Kapteyn, in Holland, has nobly undertaken to devote his spare time for seven years to superintending the reduction. Dr. Gill has laid the proposal before the Government Grant Committee. Having regard to the magnitude of the undertaking, and the probability of a conference of astronomers being shortly held in Paris to discuss the whole question, the Government Grant Committee suggested to the Council of the Royal Society that they should appoint a committee to take the subject into consideration, and the Council have acted on this suggestion. Dr. Gill intends to come to Europe in the spring, so that the committee will be able to consult him personally.

This morning I received through the Foreign Office an invitation from the Académie des Sciences for myself and some other delegate of the Royal Society to attend the conference to which I have already referred, which is fixed for April 16. I shall take the first opportunity of consulting the new Council as to their wishes.

The Copley Medal for this year has been awarded to the veteran in science, our Foreign Member, Prof. Franz Ernst Neumann, for his researches in theoretical optics and electrodynamics.

Having in his earlier years treated of crystallographic subjects almost half a century ago, he turned his attention to the theory of light. Fresnel had, with his wonderful sagacity, arrived at his celebrated laws of double refraction from the theory of transverse vibrations, aided by conceptions derived from a dynamical theory which was only in part rigorous. Cauchy and Neumann, independently of each other, were the first to deduce from a rigorous dynamical calculation, applied to a particular hypothesis as to the constitution of the ether, laws of double refraction, not indeed absolutely identical with those of Fresnel, but closely resembling them. In this case the laws were known beforehand. But in a very elaborate later paper, Prof. Neumann deduced from theory the laws of crystalline reflection, laws which appear to agree with the observations of Seebeck, and which had not been discovered by Fresnel, though some of them were independently and about simultaneously obtained by MacCullagh.

Prof. Neumann is perhaps still better known in connection with the theory of electro-dynamics, and the mathematical deduction of the laws of induced currents due to the motion of the primary and secondary conductor. He may be said to have completed for the induction of currents the mathematical treatment which Ampère had applied to their mechanical action.

Of the two Royal Medals, it is the usual, though not invariable, practice to award one for the mathematical and physical, and the other for the biological sciences.

One of these medals has this year been awarded to Prof. Peter Guthrie Tait, for his various mathematical and physical researches.

Prof. Tait is well known for his numerous and important papers in both pure mathemathics and physics. The late Sir William Hamilton regarded him as his own successor in carrying on and completing the newly-invented calculus of quaternions, of which Prof. Tait is continually making new applications. Among his investigations in the domain of experimental physics may be mentioned his determination of the conducting powers of metals for heat by a method which appears to possess special advantages, and his investigation of the effect of extremely great pressures on thermometers, undertaken with a view to deducing correct results for the temperatures at great depths in the ocean from the observations made in the *Challenger* expedition. This latter subject has led him to investigate the behaviour, as to compressibility and development of heat, of liquids and solids under enormous pressures, a subject in which he is still engaged. Before concluding, I must mention his elaborate papers on systems of knots, recently printed in the *Transactions* of the Royal Society of Edinburgh.

The other Royal Medal has been awarded to our Fellow, Mr. Francis Galton, for his statistical inquiries into biological phenomena.

Mr. Galton is well known as an explorer and geographer, and his mind is singularly fertile in the devising of ingenious instruments for various objects. Many years ago he brought before us some remarkable experiments instituted with a view to test a particular biological theory, in which rabbits of a pure variety were so connected with others of a different variety that the same blood circulated through both individuals, and the point to determine was whether this blood-relationship, in the most literal sense of the term, had any effect on the offspring. Contrary to what the theory in question led us to regard as the more probable, the result proved to be negative. It is, however, in accordance with the rules for the award of the Royal Medals, more especially the later investigations of Mr. Galton, in relation to vital statistics, that have been taken as the ground of the award. He has shown that by taking the average of a number of individuals having some condition in common, individual peculiarities apart from that condition are eliminated in the mean, and results are obtained which may be regarded as typical of that condition. One way of doing this is by his method of compound photographs. Thus we may obtain typical features of criminals of a particular kind, of consumptive persons, and so forth. By adhering to the method of averages, he has even succeeded in obtaining a mathematical expression, very closely verified in observation, connecting the mean deviation of some condition (such for example as stature) in a series of individuals, from the general mean of the same condition, with the mean deviations of the same condition in the relatives of those same individuals of different kinds, such as fathers, brothers, &c. Nor is the statistical method applicable to bodily characteristics alone. Mr. Galton has even extended it with remarkable ingenuity and originality to mental phenomena also.

The Rumford Medal has been awarded to Prof. Samuel P. Langley, for his researches on the spectrum by means of the bolometer.

A better knowledge of the ultra-red region of the spectrum, which includes the larger part of the energy of solar radiation, had long been a desideratum when Prof. Langley commenced his work upon this subject. Finding the thermopile insufficiently sensitive for his purpose, he contrived the "bolometer." This instrument depends upon the effect of temperature upon the electrical resistance of metals, a quantity susceptible of very accurate measurement; and, with its aid, Prof. Langley has been able to explore a part of the spectrum previously almost inaccessible to observation.

A result of Prof. Langley's work, very important from the point of view of optical theory and of the ultimate constitution of matter, relates to the law of dispersion, or the dependence of refrangibility on wave-length. Cauchy's formula, which corresponds well with observation over most of the visible spectrum, is found to break down entirely when applied to the extreme ultra-red.

Prof. Langley has given much attention to the important question of the influence of the atmosphere on solar radiation. The expedition to Mount Whitney, successfully conducted by him in face of many difficulties, has given results of the utmost value, pointing to conclusions of great interest and novelty.

The Davy Medal has been awarded to our Foreign Member, M. Jean Charles Galissard de Marignac, for his researches on atomic weights.

M. Marignac's numerous researches on atomic weights, which have been continued for a great number of years, have played an exceedingly important part in establishing and consolidating that ground-work of chemistry. They are remarkable for originality in devising methods appropriate to the respective cases, the most conscientious care in discovering errors which occurred in the respective operations, and indefatigable perseverance in finding means to eliminate the disturbing influences. His labours are all the more valuable because he chose for their field chiefly those elements which are most generally used in chemistry, and are most important to chemists, and on which the determination of new atomic weights is most generally made to depend.

TEN YEARS' PROGRESS IN ASTRONOMY[1]

III.

COMETS.—During the past ten years we have been favoured with an extraordinary number of comets, and while perhaps no single great step has been made, yet it is certain, I think, that our knowledge of these mysterious objects has gained a real and considerable advance.

In 1876, curiously enough, not a single comet appeared; but in 1877 there were 6; in 1878, 3; in 1879, 5; in 18 0, 5; in 1881, 8; in 1882, 3; in 1883, 2; in 1884, 3; and in 1885, 6; and so far this year, 3. Forty-four comets in all have been observed during the ten years, six of which were conspicuous objects to the naked eye, and two of them, the great comet of 1881, and the still greater one of 1882, were very remarkable ones.

The first of these will always be memorable as the first comet ever photographed. Dr. Henry Draper photographed both the comet itself and its spectrum; Janssen obtained a picture of the comet, and Huggins of its spectrum.

A number of excellent photographs were obtained of the great comet of 1882, especially by Gill, at the Cape. And it is worth mentioning that in May 1882 a little comet (not included in the preceding list, because no observations were obtained of it) was caught upon the photographs of the Egyptian eclipse.

Two of the bright comets, Wells's comet of 1881 and the great comet of 1882, approached very close to the sun, and their spectra, as a consequence, became very complex and interesting. A great number of bright lines made their appearance. Sodium was readily and certainly recognised; iron and calcium probably, but not so surely. The evidence as to the nature of the sun's corona, derived from the swift passage of the 1881 comet through the coronal regions, has already been alluded to.

The Pons-Brooks comet of 1883-84 is extremely interesting as presenting the first instance (excepting Halley's comet, of course) of one of the Neptunian family of comets returning to perihelion. There are six of these bodies with periods ranging from sixty-eight to seventy years. Halley's comet, the only large one of the group, has made many returns, and is due in 1910. Pons's comet, first observed in 1812, has now returned; Olbers's comet of 1815 is due in 1889, and the three others, all of them small, in 1919-20 and 1922.

I have spoken of them as Neptunian comets, *i.e.* their presence in our system is known to be due in some way to this planet. The now generally received theory is that they have had their orbits changed from parabolas into their present shape by the disturbing action of Neptune. Mr. Proctor has pointed out certain unquestionable, though, I think, inconclusive, objections to this view, and he proposes, as an alternative, the startling and apparently improbable hypothesis, that they have been *ejected* from the planet at some past time by something like volcanic action.

On the whole, however, the most important work relating to comets has been that of the Russian astronomer Bredichin. He has brought the mechanical and mathematical portion of the theory of comet's tails to a high degree of perfection; following out the lines laid down by Bessel, but improving and correcting Bessel's formulæ, and determining their constants by a most thorough discussion of all the accurate observations available.

It is hardly possible to doubt any longer that all the facts can be represented on the hypothesis that the tails are composed of minute particles of matter, first driven off by the comet, and then repelled by the sun. Bredichin's most interesting result, arrived at in 1878, is that the tails appear to be of three, and only three, distinct types—the long straight streamers which are due to a repulsive acceleration about twelve times as great as the sun's attraction; the second and most ordinary class of broad-curved tails for which the repulsive force ranges between one and two and a half times that of the attraction; and, finally, the short,

[1] "Ten Years' Progress in Astronomy, 1876-86," by Prof. C. A. Young. Read May 17, 1886, before the New York Academy of Sciences. Continued from p. 98.

stubby brushes which are found in a few cases, and correspond to a repulsive force not more than one-fourth the sun's attraction. Supposing, as he does, that the *real* repulsion is the same for each atom, the *apparent* repulsion, or repulsive *acceleration*, would be greater for the lighter atoms, and nearly inversely proportional to their molecular weights; and so he concludes that probably tails of the first type are composed of hydrogen, those of the second type of hydrocarbons, like coal-gas, and those of the third of iron, and its kindred metals. As to the second type, the spectroscope speaks distinctly in confirmation. Tails of the first and third types are not common, and are usually faint, and since Bredichin's result was announced there has been no opportunity for spectroscopic verification in their case.

I said his investigations had given a mathematical and mechanical explanation of comets' tails; but the *physical* question, as to the nature of the force which causes the observed repulsion, remains unsettled, though I think there is no doubt that general opinion is crystallising into a settled belief that it is electrical; that the sun is not at the same electric potential as surrounding space, and that, in consequence, semi-conducting masses of pulverulent matter, such as comets seem to be, are subject to powerful electric forces as they approach and recede from the central body. At the same time there are those—Mr. Ranyard, for instance—who forcibly urge that the direct action of the solar *heat* might produce a similar repulsive effect by causing rapid evaporation from the front surface of minute particles, charged with gases and vapours, *frozen* by the cold of outer space.

I ought not to dismiss the subject of comets without at least alluding to the numerous unprecedented and interesting phenomena presented by the great comet of 1882: first, its unquestionable relation to, but distinctness from, its predecessors of 1880, 1843, and 1668, the three belonging to one brotherhood, of common origin, and all following nearly the same path around the sun. I call special attention to this point, because Miss Clerke, in her new and admirable "History of Astronomy in the Nineteenth Century" (which I hope every one interested in astronomy will read as soon as may be), has, I think, made a mistake regarding it, assigning to the difference between the computed periods of these comets much too great an importance.

The strange elongation of the nucleus of this comet into a string of luminous pearls; the faint straight-edged beam of light that enveloped and accompanied the comet for some time; and the several detached wisps of attendant nebulosity that were seen by several observers, are all important and novel items of cometary history.

Meteors.—Time will not allow any full discussion of the progress of meteoric astronomy. It must suffice to say that the whole course of things has been to give increased certainty to our newly-acquired knowledge of the connection between meteor-swarms and comets, and to make it more than probable that a meteor-swarm is the result of the disintegration and breaking-up of a comet. This seems to be the special lesson of the Bielids, the re-appearance of which, as a brilliant star-shower last November, attracted so much attention. In an important paper read before the National Academy of Sciences, last April, Prof. Newton pointed out how all the facts connected with the division into two of Biela's comet forty years ago, its subsequent movements and disappearance, and the meteoric showers of 1872 and 1885, and especially the peculiar features of this last shower, all conspire to enforce this doctrine.

I mention, doubtfully, in this same connection the recent supposed discovery by Denning of what are generally alluded to as "long radiants": systems of meteors, *i.e.*, which for weeks, and even months, together, seem nightly to emanate from the same point in the sky. One of these radiants, for instance, the first of half a dozen described by Mr. Denning, is about $1\frac{1}{2}°$ north of β Trianguli, and the shower appears to last from July to November, at the rate of perhaps one or two an hour.

If the fact is *real*, it follows inevitably that, disseminated through all the space in which the earth is moving, and has been moving for several years—not less than 1,000,000,000 miles—there are countless meteoroids moving in parallel lines, and with a velocity so great that the earth's orbital motion of 19 miles a second is absolutely insignificant as compared with theirs. Their speed must be many hundreds of miles per second. This may be true, but I own I am not ready to accept it yet. The observations indicate directly no extraordinary swiftness. Mr. Proctor, whose mind appears at present to be chiefly occupied by the idea that suns and planets are continually bombarding their neighbours (or at least do so at some stage of their existence), ascribes such meteors to the projectile energies of some of the "great" stars. But there is not time to discuss his notion, and it is hardly necessary, until it has begun to receive somewhat more extensive acceptance. I am not aware that, so far, he has any converts to his theory of comets and meteors.

Stars.—Want of time will also prevent any adequate treatment of the recent progress of stellar astronomy.

Two great works in the determination of star places must, however, be mentioned. One is the nearly completed catalogue of all the northern stars, down to the ninth magnitude, begun almost twenty years ago, under the auspices of the Astronomische Gesellschaft, by the co-operation of some fifteen different observatories. The observations are now nearly finished, and several of the observatories have already reduced and published their work. A very few years more ought to bring the undertaking to a successful end.

Another similar work, almost, though not quite, as extensive, is the great catalogue of southern stars, made at the Observatory of Cordova by our own Dr. Gould and his assistants. He himself, with his own eyes, observed every star of the whole number—nearly 80,000—his assistants reading the circle and making the records; and the whole has been reduced, printed, and published within the space of twelve years—a veritable labour of Hercules, for which, most justly, our National Academy has awarded him the Watson Medal. He had already, some years ago, received the gold medal of the English Royal Astronomical Society, for the "Uranometria Argentina," an enumeration of all the naked-eye stars of the southern hemisphere, with their approximate positions and estimated magnitudes. This, however, was only a sort of preliminary by-play, to pass the time while waiting for the completion of his observatory and meridian-circle.

We must mention also the remarkable star-charts made by Dr. Peters, of Hamilton College, of which he has already published and distributed at his own expense about twenty, and more are soon to follow.

But the old-fashioned way of cataloguing and charting the stars is obviously inadequate to the present needs of astronomy, and a new era has begun. While, hereafter, as hitherto, the principal stars, several hundred of them, will be observed even more assiduously and carefully than ever before, with the meridian-circle or similar instruments, the photographic plate will supersede the eye for all the rest. It is now easily possible to photograph stars down to the thirteenth or fourteenth magnitude, and to cover a space of $2\frac{1}{2}°$ square on a single plate. The remarkable thirteen-and-a-half-inch instrument constructed by the Henry Brothers, for the Paris Observatory, and first brought into use last August, does this perfectly. Instruments very similar, but smaller, lately set up at Harvard College, at the Cape of Good Hope, and at Liverpool, while they do not reach so faint stars, cover more ground at a time.

Negotiations are already under way to secure the co-operation of a number of observatories for a photographic survey of the heavens; and it is probable that, after some preliminary consultation and before very long, it will be actually in progress. According to Struve's estimates, it could be accomplished in about ten or twelve years, even on the Paris scale, by the combined efforts of fourteen or fifteen establishments. Orders have already been given to the Henry Brothers, by Dom Pedro, of Brazil, and Mr. Common, of England, for instruments precisely like the one at Paris. Americans, and New Yorkers especially, may well take a peculiar interest in astronomical photography, since it was at Cambridge, in 1861, that the first star-photographs were ever made, and here, in New York, Rutherfurd and Draper were among the earliest and most successful workers: in the observatory above us is now mounted the very instrument with which Rutherfurd made his unrivalled pictures of the moon and his plates of the Pleiades, more than twenty years ago.

During the past ten years, stellar photometry has become almost a new science. Its foundations, indeed, were laid by J. Herschel, Seidel, Wolff, and Zöllner, before 1870, and the magnitudes of some two hundred stars had been measured, and the law of atmospheric absorption determined. But the great work of Pickering, at Harvard, in the invention and perfecting of new instruments, and his "Harvard Photometry," which gives us a careful measurement of the brightness of all the naked-eye stars of the northern hemisphere, marks an epoch. And he is pushing on, and has already well under way the measurement of the 300,000 stars of Argelander's "Durchmusterung." Nor must we omit to mention Pritchard, of England, whose name has just been joined with Pickering's by the Royal Astronomical Society, in the bestowal of their gold medal for his wedge-photometer and the photometric work done with it. The "Harvard Photometry," and the "Uranometria Oxoniensis" together will carry down to all time the record of the present brightness of the stars. They will be especially valuable as data for determining changes in stellar brilliancy.

During the past ten years the number of variable stars has risen from about 100 to nearly 150; and our knowledge of their periods and light-curves has been greatly improved. In America, Chandler and Sawyer, of Boston, and Parkhurst, of this city, have done especially faithful work. During the ten years we have had two remarkable "temporary stars," as they are called —first the one which, in November 1876, in the constellation of Cygnus, blazed up from the ninth magnitude to the second, and then slowly faded back to its former brightness, but to a *nebulous* condition, as shown by its spectrum; then also the one which, last autumn, appeared in the heart of the nebula of Andromeda as of the sixth magnitude (where no star had ever been seen before), slowly dwindled away, and is now beyond the reach of any existing telescope. Perhaps, too, we ought to mention another little ninth-magnitude star in Orion's club, which last December rose to the sixth magnitude, and is now fading; it seems likely, however, from its spectrum, that this is only a new variable of long period.

As to star-spectra, a good deal of work has been done in their investigation with the ordinary stellar spectroscopes by the Greenwich Observatory, by Vogel at Potsdam, and by a number of other observers,—work well deserving extended notice if time permitted. But the application of photography to their study, first by Henry Draper in this city, and by Huggins in England, is the important new step. By the liberality of Mrs. Draper, and as a memorial of her husband, his work is to be carried on with the new photographic instrument and method just introduced by Prof. Pickering at Cambridge. He is able to obtain on a single plate the spectra of all the stars down to the eighth magnitude in the group of the Hyades, each spectrum showing under the microscope the characteristic lines quite sufficiently for classification. A different instrument is also to be built with the Draper Fund, which will give single star-spectra on a much larger scale and in fuller detail.

During the decade, the stellar parallax has been worked at by a number of observers. Old results have been confirmed or corrected, and the number of stars whose parallax is fairly determined has been more than doubled. The work of Brunnow and Ball in Ireland, of Gill and Elkins at the Cape of Good Hope, and of Hall, at Washington, deserves especial mention. A new heliometer of seven inches aperture has been ordered for the Cape Observatory, and when it is received, a vigorous attack is planned by co-operation between that observatory and that of Yale College, which possesses the only heliometer in America.

During the ten years, our knowledge of double stars has been greatly extended; several observers, and most eminent among them Burnham, of Chicago, have spent much time as hunters of these objects, and have bagged between one and two thousand of them. Several others, especially Doberck in England, and Flammarion in France, have devoted attention to the calculation of the orbits of the binaries, so that we have now probably about seventy-five fairly well defined.

In the study of the nebulæ, less has been done. Stephan at Marseilles and Swift at Rochester have discovered many new ones, mostly faint, and Dreyer, of Dublin, has published a supplementary catalogue, which brings Sir J. Herschel's invaluable catalogue pretty well down to date. The studies of Holden upon the great Orion nebula and the so-called "trifid nebula" deserve special mention, as securely establishing the fact that these objects are by no means changeless, even for so short a time as twenty or thirty years; also the discovery of a new nebula in the Pleiades by means of photography.

Observatories.—During the ten years, a considerable number of new observatories have been founded. Abroad, we mention as most important the observatories for astronomical physics at Potsdam, in Prussia, and at Meudon, in France, also the Bischoffsheim Observatory at Nice and its succursal in Algiers. The great observatory at Strasburg can hardly be said to have been founded within the period indicated, but the new buildings and new intruments and new efficiency date since 1880. We ought not to pass unnoticed the smaller observatory at Natal, in South Africa, and the private establishments of von Konkoly at O-Gyalla, of Gothard at Hereny (both in Hungary), and of the unpronounceable gentleman Jedrzejewicz at Plonsk, in Poland, and the observatory at Mount Etna, from which, however, we have no results as yet.

In the United States, we have the public observatories at Madison, Wis., at Rochester, N.Y., and at the University of Virginia, and the, as yet, unfinished Lick Observatory in California: also a host of minor observatories connected with institutions of learning, and mainly designed for purposes of instruction; such establishments have been founded within ten years at Princeton, at Northfield, Minn., at South Hadley, Ms., at Beloit, at Marietta, at Depauw, at Nashville, and at St. Louis, also at Franklin and Marshall College, and at Doane College, in Nebraska, at Columbia College, Ann Arbor, and Madison, Wis., and at one or two other institutions which escape me for the moment. Several others are also at this moment in process of erection. Every one of them has a telescope from six to thirteen inches aperture, with accessory apparatus sufficient, in the hands of an astronomer, for useful scientific work.

Instruments.—A large number of new instruments of great power have been constructed. We mention the great thirty-inch refractor of Pulkowa, the twenty-six-inch of Charlottesville, and the twenty-three inch at Princeton, for all which the lenses were made by our own Clark. We add the great Vienna twenty-seven-inch telescope by Grubb, and the twenty-nine-inch object-glass by the Henrys, made for the Nice Observatory, but not yet mounted; also the nineteen-inch telescope at Strasburg by Merz. Grubb has also at present a twenty-eight-inch object-glass under way for the Greenwich Observatory, and Clark has nearly completed the monstrous thirty-six-inch lens for the Lick Observatory. There never was a decade before when such an advance in optical power has been made.

Great *reflectors* have been scarce, the only ones of much importance constructed during the time being the twenty-inch instrument at Algiers, and Mr. Common's exquisite three-foot telescope, which he has lately sold to Mr. Crossley in order to make way for one of five feet diameter, now, I believe, under construction. The old three-foot and six-foot instruments of Lord Rosse have been improved in various ways, and are still in use,—especially in work upon lunar heat. Among newly-*invented* instruments, we mention the meridian-photometer of Pickering, the wedge-photometer of Pritchard, the almucantar of Chandler, the concave diffraction-grating of Rowland, and the bolometer of Langley—all, but one, American. Repsold's improvements in the micrometer, in the heliometer, and in the mounting of equatorials should also be mentioned here.

As to new astronomical methods, enough has been already said about photometry and astronomical photography. It is plain that we are entering upon a new era.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

THE examination for the Sheridan Muspratt Chemical Scholarship at University College, Liverpool, will begin on December 9. The Scholarship is of the value of 50*l*. per annum, tenable for two years. Candidates should apply to the Registrar before December 6.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, November 22.—M. Jurien de la Gravière, President, in the chair.—On the life and work of L. R. Tulasne, by M. Ed. Bornet. The paper contains a somewhat detailed account of the labours of this eminent botanist, who was born at Azay-le-Rideau (Indre-et-Loire) on September 12, 1815, and died on December 2, 1885. Appended is a list of the scientific publications of MM. Louis-René and Charles Tulasne.—On ammoniaco-magnesian phosphate, by M. Berthelot. In continuation of his previous researches on the colloidal and crystallised states of the earthy phosphates, and especially of the phosphate of magnesia, the author here studies the double ammoniaco-magnesian phosphate, determining the conditions of formation of this compound in chemical analysis.—The Montgaudier Cave, by M. Albert Gaudry. The author describes a visit he recently paid to this cave, which is situated in the Charente district, and which has revealed several objects of an artistic character, dating from the close of the Quaternary epoch, when the large fauna of extinct species had already mostly disappeared. But some remains, such as pieces of ivory embellished with carvings of the aurochs and other animals, seem to have been executed at an earlier period, while the cave-dwellers were still struggling for existence with the mammoth, with *Rhinoceros tichorhinus*, the cave-bear, cave-lion, and large hyæna.—On glycose, glycogene, and glycogeny, in their relation to the production of heat and of mechanical labour in the animal system, by M. A. Chauveau. In this first physiological study of these elements, the author deals more especially with the generation of heat in the organism while in a state of repose. The reasons are set forth which lead to his broad generalisation regarding the preponderating part played by the glycose of the blood in organic combustions, source of animal heat and of muscular energy. It is now fully established that the absorption of glycose in the capillaries during the transformation of arterial into veinous blood is connected with the respective activity of the attendant combustions in the several organs.—Some remarks on the determination of mean values, by Leopold Kronecker. It is shown that in a converging series of real terms $\phi_1 + \phi_2 + \phi_3 + \ldots$ with positive real quantities $\psi_1, \psi_2, \psi_3 \ldots$ increasing with n beyond all limit, the limit of the expression—

$$\frac{1}{\psi_n}(\phi_1\psi_1 + \phi_2\psi_2 + \phi_3\psi_3 + \ldots + \phi_n\psi_n)$$

for increasing values of n is equal to zero.—On the movement of an indefinite and perfectly elastic fluid, by M. N. Marin. The object of this study is to complete the law of Mariotte by another described as the law of elasticity for perfectly elastic and completely free fluids. In a fluid so constituted, it is laid down that all contraction determined by any cause whatsoever acting in a single direction, is instantaneously propagated in all other directions.—On the movement of a cord in a fixed plane, by M. Appell.—On the algebraic integrals of Kummer's equation, by M. E. Goursat.—Analytical demonstration of a theorem relating to orthogonal surfaces, by M. Paul Adam. The theorem here dealt with is that of M. Maurice Lévy regarding a group of surfaces in an orthogonal system, and by him demonstrated on purely geometrical considerations.—On the unequal movement of a compressed gas in a reservoir freely discharging into the atmosphere, by M. Hugoniot.—On an apparatus by which the time may be communicated to the performers out of the conductor's sight, by M. J. Carpentier. The apparatus here described has been constructed at the request of the directors of the Paris Opera. It is based on the principle of visible signs, depending on a purely optical illusion, and producing the impression of an ordinary conductor's hand beating time. It is thus free from the defects inherent to the various electric appliances hitherto devised for the same purpose.—On a means of increasing the power of fluid and electric agencies, by M. Charles Cros. In this process a return is made to the old idea involved in the expression "electric fluid," and the wires are regarded as analogous to elongated tubes through which pressure is transmitted. The experiment was suggested by the author's researches on transmissions through more or less elastic tubes containing air or water.—On the tension of saturated vapour, by M. P. Duhem.—On the physical properties of mercury, by M. Marcellin Langlois. On the assumption of a mono-atomic molecule of mercury, the author determines its heat of evaporation, its specific heat, compressibility, and heat of fusion.—Actinometric studies, by M. E. Duclaux.—A new process of volumetric analysis for powdery zinc (*gris d'ardoise* of la Vieille Montagne), by M. Fréderic Weil. By the process here described, 100 gr. of this substance yield 65·3 gr. of pure zinc.—Action of the alcohols on the protochloride of gold and phosphorus, by M. L. Lindet. Here are described the preparation and properties of two chlauroso-phosphorous ethers—ethylic and methylic ether.—On the Russian petroleums, by M. J. A. Le Bel. The chief element of the petroleum of Baku, at the eastern extremity of the Caucasus, are naphthenes, C_nH_{2n}, and naphthylenes, C_nH_{2n-2}; and their salient characteristic is that they do not fix bromine.—On the heats of neutralisation of malic and citric acids and of their pyrogened derivatives: remarks on the numbers obtained, by MM. H. Gal and E. Werner.—On certain correlations between the modifications experienced by species of different genera subjected to the same influences, by M. Fontannes. Several analogous modifications are noted pervading many species of different genera throughout the geological record; but no theory is advanced to explain the coincidences.—On a new genus of parasitic Copepod, by M. Eugène Canu. This new genus is a parasite of the Synascidians, and abounds on the *Morchellium argus* (Milne-Edwards) frequenting the Wimereux district.—On the anomalous formations of the Menispermeæ, by M. Gérard.—Observations on the plaster added to new wines in the South of France and other parts of Europe, by M. A. Audoynaud.—Note on the coarse marine limestone formation of the Provins district (Seine-et-Marne), by M. Stanislas Meunier.—On the Devonian system of the Eastern Pyrenees range, by M. Ch. Depéret.—On the pleromorphoses of the quartz of Saint-Clément (Puy-de-Dôme), by M. Ferdinand Gonnard.—Description of a variety of Carphosiderite, by M. A. Lacroix. The optical properties of this mineral, which was found in the neighbourhood of Mâcon (Saône-et-Loire), are described.—On the conditions of form and density of the terrestrial crust, by M. A. de Lapparent. It is argued that the generally-accepted views regarding the symmetrical flattening of the globe at the poles is far from proved, and it is suggested that in the southern hemisphere there exists an inaccessible antarctic continent presenting a different conformation in this respect from that of the northern hemisphere.—On the mode of formation of the Newfoundland banks, by M. J. Thoulet.—On the progressive desiccation of lacustrine basins in dry climates, by M. Venukoff.

COMPARATIVE ANATOMY OF VERTEBRATES

Elements of Comparative Anatomy of Vertebrates. Adapted from the German of Robert Wiedersheim, by W. Newton Parker. (London: Macmillan and Co., 1886.)

IN examinations for the higher degrees and diplomas in science and medicine, candidates are required to show that they possess not only a knowledge of the anatomy of the chief types of the animal kingdom, but also of comparative morphology. Indeed, with respect to medicine, this latter is the more important, especially the morphology of vertebrates. For some time past English students have found themselves considerably handicapped by the want of a short and concise text-book on this subject, to enable them to meet the requirements of Examination Boards; the text-books available for their perusal being generally of too advanced a character, and better suited for the use of those wishing to make comparative anatomy a lifelong study, than for students whose ulterior aim is the practice of medicine or some of its branches. German students, notwithstanding the numerous works on comparative anatomy published in that country, seem to have been equally as ill off for a suitable text-book as their English *confrères.* So impressed was Prof. Wiedersheim that his "Lehrbuch der Vergleichenden Anatomie," a work well known and appreciated by comparative anatomists in this country, and one of the leading works on the subject in Germany, was not a suitable book for ordinary students of medicine, that before bringing out a new edition of it he published a smaller one, entitled "Grundriss der Vergleichenden Anatomie der Wirbelthiere," expressly to meet their requirements. The number of English students sufficiently acquainted with German to be able to take advantage of this work in the original is unfortunately very small, but to those who could do so it has proved to be of great assistance. So well has the German edition fulfilled the object of its author, that the idea occurred to others besides Mr. Parker, that the translation of so useful a work into English was very desirable in the interests of English-speaking students, though it cannot but be a matter of regret that this should be necessary, and probably would not have been so, were English students as well acquainted with the German language as its importance demands they should be.

Throughout the work before us Mr. Parker has retained the original plan of Prof. Wiedersheim's "Grundriss," but a considerable number of additions to and modifications of the original text have been introduced. For some of these he acknowledges that he is responsible, while others have been inserted on the suggestion of Prof. Wiedersheim, who has also revised the whole work previously to its publication.

The work begins with a general introduction, in which the nature and meaning of comparative anatomy is explained, a short outline of the embryological development and structural plan of the vertebrate body is sketched out, and a table is given containing the general classification adopted by the authors throughout the work, of the principal existing vertebrate groups; there is likewise a second table from H. Credner, showing the gradual development of the Vertebrata in time. This part of the work occupies only 15 pages, and is well illustrated by means of nine woodcuts. It is preceded by a list of general works on comparative anatomy and embryology.

The comparative anatomy of vertebrates, constituting the special part of the work, and occupying 315 pages—the remainder of the book—is dealt with under nine sections, arranged according to the different organs of the body. These are treated of in the following consecutive order: integument, skeleton, muscular system, electrical organs, nervous system, organs of nutrition, organs of respiration, organs of circulation, and urino-genital organs. This part of the work is illustrated by 320 woodcuts, most of which are taken from the German edition, but some are new. After each section is appended a short bibliographical list of the more important and recent works relating to the subject under consideration in the chapter.

In treating each section the plan adopted is to begin with a few general introductory remarks, applicable to the whole of the Vertebrata, on the anatomy of the organ or set of organs to be dealt with in the section, and then to proceed to the consideration of its special characters in the different groups of vertebrates. By two kinds of type being used, one larger than the other, the more essential characters of organs or structures are readily distinguishable by the elementary student from the more theoretical and detailed information regarding them printed in the smaller type. The more important words and passages are further indicated by the use of heavy black and spaced types. The former we think might well have been dispensed with, as the use of so many kinds of types tends rather to confuse than render clear. The use of spaced type for important passages and words, though extensively used in German text-books, is only just beginning to be adopted by English authors and printers in place of italics, on which it is a very great improvement. We must, however, enter a decided protest against the use of clarendon type for any purpose except headings, on account of the blotted and disfigured appearance it gives to the pages and on account of the distraction it produces on the reader. Notes explanatory of the text are frequently added at the foot of the page throughout the whole work; that this should have been done is, we consider, a mistake. The introduction of footnotes into any work, and particularly such a work as the present, is extremely objectionable, and should be resorted to as seldom as possible except for references to other publications, where its use may be permissible. Nor is there any excuse in the present instance why so many footnotes should have been introduced, when by the use of a few lines of the smaller type in the body of the page it could have been avoided.

Throughout the text there is a want of uniformity in the manner in which the different kinds of type are used, which will probably be corrected in a new edition; thus, for example, on p. 49 the word "Snakes" is printed in spaced type, whereas three lines lower down "Lizards," another group of Reptiles, is printed in ordinary type, as are also the words "Birds" and "Mammals" on the next page. There are also some descriptions of structures which might be improved in another edition, so as to make the meaning clearer to the student; as an example of this, the history of the development of hair may be mentioned. The brevity of some of the descriptions is, as the authors state, to some extent made up for by the number of woodcuts, but in some cases we think it would have been well had a few lines more been added, even had it been necessary to curtail some of the small print; thus on the first page surely it would have been well to have devoted a little more space to explaining what is meant by the words "ontogeny" and "phylogeny," terms which are constantly referred to throughout the work. It is true that this is also a fault of the original German edition, but as the translator has not professed to adhere strictly to the German text this is a liberty which he might have taken.

We regret to see the words ecto-, meso-, and endoderm used by Prof. Wiedersheim in the original German changed to epi-, meso-, and hypoblast in the English edition, as we consider the terms used by German and other Continental morphologists preferable to those employed by many English writers. We also traverse the statement in the footnote, presumably Mr. Parker's, that the former terms "are applied to the corresponding layers in the adult animal." The terms are respectively synonymous when applied to vertebrates; the skeleton or muscular system of a rabbit is not spoken of as its mesoderm, but as being of mesodermic or mesoblastic origin.

In describing the homologies of the carpus and tarsus, we quite approve of the position the authors have taken with regard to a subject of much controversy on which further investigations may throw more light, but we think in the general considerations regarding the derivation of limbs from fins the history of the evolutionary changes which have taken place is stated much more definitely than the state of our knowledge justifies. That the theory with which Prof. Wiedersheim's name is connected should be brought prominently forward was to have been expected, but no reference is made to other views, such as those of Gegenbaur and Götte, which, in the uncertain state of our knowledge of the subject, might have been expected. We notice that the pentadactyle form of *Equus* found by Marsh has been omitted in the illustrations of the ancestral forms of the horse's foot, and referred to only doubtfully in the text.

In the section on organs of circulation, the heart and its vessels are excellently described, and the introduction occasionally of coloured illustrations makes the subject as clear as could be desired, but the description of the formation of the circulation in the liver and the modifications of the trunk vessels which have occurred in the evolution of the higher from the lower vertebrates, is very short and meagre.

The criticisms which we have passed, however, are not made with the view of finding fault with an excellent and creditable work, but are expressed in the hope that in future editions it may be made more useful for the purpose for which it is intended.

In conclusion, we heartily thank Mr. Parker for introducing to English students a work which we are confident will prove a great assistance to them in their studies, and by perusal of which they will be enabled to understand the anatomy of man in a much more comprehensive manner than they could from a study of human anatomy alone.

J. G. G.

SCIENCE IN NORWAY

Nyt Magazin for Naturvidenskaberne. "New Journal of Natural Science." (Christiania, 1886.)

THE four volumes of this admirable publication which have been sent to us by the Norwegian publishers, include the twelve numbers printed since 1882, and thus complete the third series of the magazine, which, notwithstanding its title of "New," is the oldest Norwegian publication of its kind.

The subjects treated of in its pages belong, with few exceptions, to the general natural history of Norway, in which department special attention is due to Herr Leonard Stejneger's paper on the "Ornithology of Western Norway," as well as to the various interesting contributions of Dr. Robert Collett. To the latter eminent naturalist, well known for his able work "On the Fishes of Norway" (1874), the magazine is indebted for several communications regarding the number and distribution of various species of fishes, first observed in Norway between 1879 and 1883, while in his papers on the character and species of mammals indigenous to Norway, he has contributed much useful information in reference to the Norwegian beaver (*Castor fiber*). From the author's observations, it would appear that the injury done to the forests by these animals in bringing down trees for the construction of their huts in no way justifies the indiscriminate destruction of the beaver, which had long been allowed to go on unchecked in Norway. This view has of late been so generally accepted that the Norwegian Government have been induced to appoint a close time of nine months in the year, during which the shooting or trapping of the beaver is legally prohibited. In special cases, and in certain districts, the local magistrates may even extend this period to ten years if they see reason to apprehend the extermination of the animal.

Norwegian geology and mineralogy are well represented in these volumes, Dr. Kjerulf having added to his labours of an editor those of a diligent contributor, and besides several short papers on the finer mineralogical specimens derived from the Storvarts and other important Norwegian mines—a subject which is also well treated by Herrn Olsen, Münster, and Knudsen—he has enriched the journal with interesting monographs on the local geology of the country, including notices of the dislocations observable in the Christiania valley; the character of the formations at Mjösen-lake which have been brought to light through recent railway-cuttings; and the inclination of the principal lodes on Ekersund. Dr. Hans Reusch describes at length the fall of meteors observed at Vaage in Tysne Island on May 20, 1884, giving useful tables of meteoric falls, whose dates are well attested, between 1784 and 1884. Besides various other papers, Dr. Reusch contributes some interesting geological notices of the districts of Christiania, Valders, and Viksnes, and considers at some length the evidence afforded by the fjelds of Western Norway, of the duration of the Ice age, and the local extension of glacial action in Norway.

The marine zoologist will find much valuable matter in the interesting reports by Messrs. Danielssen and Koren of the Asteridea, collected in the Norwegian North Atlantic Expedition. These papers are a *résumé* of the complete volume, which will appear later on as part of the Collective Report of the Expedition. Of the 20 genera and 40 species collected, 4 genera and 11 species are new to science. Numerous specimens of the Pedicellaster found in West Greenland, and described by Dr. Sladen as new, to which he gave the specific name of Palæocrystallus, is identified by Dr. Danielssen as *P. typicus* of Sars. Extreme importance attaches to the discovery and careful examination of a specimen of an asteroid—unfortunately the only one secured—which differs from others of the family by having a central dorsal appendage, generally erect, but capable of motion. This curious Echinoderm, to which Messrs. Danielssen and Koren give the name *Hyaster mirabilis*, is conjectured by them to represent a larval or developmental stage of the Crinoidea, and after a careful study of this stalk-like appendage they hazard the conjecture that further investigations may lead to the discovery that the Asteridea are in fact developed from the Crinoidea. Equally interesting, if less important, is the re-discovery of the Greenland "Clusterpolyp" of Ellis, the "*Zoophytum grönlandicum*" of Mylius. The specimens examined by these earlier naturalists have long disappeared, and for more than a hundred years no others were found. The *Challenger* Expedition brought back several forms of an Umbellula, one of which Prof. Kölliker considered to be of the same species as the lost specimens of Ellis and Mylius; the Norwegian naturalists are of opinion, however, that all the specimens found are mere varieties of *Umbellula encrinus*, to which they ascribe a wide geographical range.

In conclusion, while we desire strongly to recommend the *Nyt Magazin*, it may not be out of place to mention that several of the most interesting papers on local Norwegian geology are written in German, and that the highly important results of the recent Norwegian North Atlantic dredgings are given by Dr. Danielssen in English, under the title of a "Preliminary Report" of the Expedition. The magazine, which is under the joint editorship of Professors Kjerulf, Danielssen, Mohn, and Hiortdahl, is printed in the Latin type now so generally used in the Norwegian press, and is copiously illustrated by well-drawn woodcuts, and excellent plates of the animals described.

OUR BOOK SHELF

Acta Mathematica. (Stockholm. Various dates.)

THIS journal, which has already won for itself the reputation of being one of the leading mathematical journals, not of the North merely, but of the world, sprang into life at the end of 1882, is published at Stockholm, and has all along been under the able editorship of Prof. G. Mittag-Leffler, assisted by all the foremost mathematicians of Sweden, Norway, Denmark, and Finland. Its object is stated to be to gather and publish such mathematical works as contribute to the development of the science by the novelty either of the results obtained or of the methods employed.

The seven volumes which have been issued contain papers by some of the foremost Continental mathematicians: the sole contribution, we believe, in English is furnished by an American writer, Mr. G. W. Hill, and is entitled "On the Part of the Motion of the Lunar Perigee which is a Function of the Mean Motion of the Sun and Moon" (this paper occurs in vol. viii., which is in course of publication). There are in all, in the complete volumes, 107 papers, in almost every department of the science.

It may be in the recollection of our readers that Oscar II., King of Sweden and Norway, who is styled "Special Protector of the Journal," has instituted a great mathematical prize for an important discovery in higher analysis, the particulars of which have appeared in full detail in our columns (vol. xxxii. p. 302); the prize works are to be published in the *Acta*.

The Methods of Glass-Blowing. By W. A. Shenstone. (Rivingtons, 1886.)

NOT only the student who is entering, or has just entered, that mystic land of chemical research, but also the ordinary student of chemistry who wishes to be more than a mere beginner, or a book-chemist, will hail with great joy the appearance of this little book on glass-blowing. We have not many good professional glass-blowers in this country, and, as the author says, it is a difficult if not impossible thing to get any instruction in glass-blowing; and, as a result, the great bulk of chemical students are as dependent on the dealers in glass ware as the bulk of amateur photographers are on dry plates and other things in that connection.

Most students even in our hardest working laboratories have some time to spare in which they might practise some of the more useful and simple methods of making glass apparatus mentioned and described in this little book.

Apart from the immediate utility of being able to make one's glass apparatus in the laboratory, and the help it is in almost any form of chemical or physical research, it cannot fail to be also indirectly useful to a student on his transplantation to a works or the superintendence of some technical operation, and will give him what is so very desirable, in addition to that of the purely chemical manipulation of analysis, a feeling of confidence in overcoming mechanical difficulties.

In the introduction is a description of a suitable working-place, blow-pipe, and bellows—things which are seldom to be found fit to use in our laboratories—and the blow-pipe flames; after which the varieties of glass mostly used, and the actual operations involved in the construction of most glass apparatus, in which glass tubes are the main parts, are very plainly described, being also in many cases illustrated with diagrams of the different stages. The last chapter is devoted to "calibrating and graduating glass apparatus," operations we think every student who gets as far as quantitative analysis should be able to perform in a decent manner.

We most thoroughly recommend this little book to students who intend to become chemists, and hope the proportion of those who can blow a respectable bulb will soon be increased. At present it is about ·1 per cent.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Two Hours with a "Subject Index"

THERE has appeared within the year, under the title of "A Subject-Index to the Modern Works added to the

Library of the British Museum in the Years 1880-85," the latest of the series of indexes published under the auspices of our great national library. Having recently had occasion to consult the same with reference to certain biological works, I experienced so much difficulty in finding what I wanted, that I thought it worth while to inquire more fully into the trustworthiness of the volume as an aid to the working naturalist. I append my notes, in the interest of workers in a field the literature of which is already overburdened.

The book is printed in unnecessarily large type, whence there results a ponderous volume of 1044 pages quarto. Upon the immensity of the task before the bibliographer set to compile such a work I need not comment. If the duty be well performed, there can only result a product useful to all, and helpful to the specialist; if otherwise, confusion becomes confounded, and there ensues to the worker loss of time, if not actual disaster.

Printers' errors and minor inaccuracies are to be expected in a work of the kind, and any such compilation must of necessity be faulty. It is not surprising, therefore, to find "travel" for "translation" in recording the title of Scott Russell's work, on p. 1016. Other similar defects could be quoted, but why are the press-marks occasionally omitted? surely they are next in importance to the titles themselves? The compositor cannot be at fault here.

The compiler sets forth his scheme in a short preface, by no means a bad one if followed. One of the chief provisions reads thus: "Headings and sub-headings are in strictly alphabetical order; precedence being given under each to the larger and more important works." It is in the execution of this self-imposed dictum that the compiler is seen at his best. Who is to be the judge of the relative merits of the collected works, and what is to be the standard of comparison? Presumably, the compiler performs the difficult task in person, but it is indeed well that his method is not revealed, for Huxley's "Crayfish" heads the list of general works upon Mollusca (p. 653), and Miss Buckley's "Life and her Children" that upon Micro-organisms. The thing must be a joke! Nothing of the kind!! "Corallinen Algen" brings up the rear of Corals (p. 212), while "Les Batrachospermes" are exalted to an equality with the Batrachians—a truly novel means this of demonstrating the unity of the biological sciences. The aforenamed inaccuracies amount almost to incredibilities, and it is difficult to realise that they are perpetrated in earnest. It is inconceivable that they can have resulted from mere carelessness; but, even were that so, the fact that they exist at all would be sufficient in itself to disqualify the compiler. We can only regard them as the natural outcome of giving to one man the work of half a dozen; they disfigure the work, and shake our confidence in much that remains. A little less pardonable, perhaps, is the relegation of "Der Tasman-Gletscher" to the Column Tasmania.

The choice of headings is often ill-advised. Four works are recorded upon the Polyzoa; these are equally divided between Polyzoa and Bryozoa, to neither of which headings is there a cross-reference. Writings upon organisms in air generally are distributed between sections Air and Atmosphere, Micro-organisms, and Bacilli and Bacteria, with no cross-references. Papers dealing with the broadest generalisations and the subtlest of details are muddled together regardless of system; while under Micro-organisms there is a cross-reference to Infusoria, sole possessor of which department is Kent's well-known Manual. Section Palæontology is especially introspective. It is divided into the sub-heads General, Bibliographical, Collections of Fossils &c., Fossil Fauna, and Flora—a sufficiently inconsistent arrangement in itself. Conspicuous among the general works is Brongniart's "Recherches sur les graines fossiles silicifiées." A knowledge of the publications of his own department ought certainly to be expected of the compiler, through whose hands the covers of the said works must surely pass. But no; for while there has been recorded under the last-named heading Rupert Jones's "Catalogue of Fossil Foraminifera," we look in vain for the companion volumes of Hinde and Lydekker, both of which were published within the period embraced. There is here something akin to contempt for authority! Marsh's "Odontornithes," divorced from Palæontology, finds a home among the Birds.

Having found that the leading tenet of the scheme was violated—that relating to the precedence of important works—I turned next to the second one. It reads: "All books are, so far as possible, grouped together according to their language, in the following order—English, French, German, Italian. . . . There are, however, some deviations from this system—for example, in the history of each country the titles follow each other in chronological sequence, irrespective of language." How the two methods of arrangement thus vaguely formulated are to be simultaneously adopted, we are not informed; and in this ingenious attempt to combine two schemes into one neither has been adhered to—both have suffered. A cursory glance at some of the more important sections, *e.g.* Birds, shows that the conditions have not been in the least fulfilled, so far as pertains to precedence of language; while, to go afield, we find under Clergy, Priesthood, &c., a unique arrangement in which the languages run thus—Spanish, English, German, French, Italian, English, *ad finem*. Where, here, is the professed patriotism? It deserts the author under the inspiration of Clergy, Priesthood, &c., and leaves him reckless. What now of the chronological sequence? One turns instinctively to various historic headings. In none of those examined did I find the exception to be the rule.

The major scheme nullified, the preface becomes a blank; but the details of the superstructure are no more to be relied upon than is the foundation itself. Under Insects, to which the reader is referred from Entomology, there are titles in abundance in which the two catchwords occur; but he looks in vain for references to the fact that the majority of entomological papers are scattered among Coleoptera, Diptera, Hymenoptera, Lepidoptera, Ants, Wasps, Bees and Bee-keeping, and other headings. The Colorado Beetle figures under that heading and under Potato, but not under Coleoptera; while, to complicate matters, a German and an English work upon the subject appear under Potato, the place of the former being, under Colorado Beetle, usurped by a Spanish rival. Fish and Fisheries embraces all branches down to Oyster-Culture, but why not Salmon Fisheries? It appears to suffice that they should take shelter under Salmon, with no cross-references. A special heading is set up for Angling, but several definite works thereon are to be found only under Fish and Fisheries, no references being given under Angling.

Titles of works are not unfrequently repeated, and that unnecessarily. For example: Morris's "Letters about Birds" occurs under Birds (sub-headings—General, and Great Britain and Ireland); Dixon's, Swaysland's, and Watkins's books are not under their appropriate headings; while Patterson's "Birds, Fishes, and Cetacea frequenting Belfast Lough," which should be under Fauna, Local, is misplaced. Under the last-named heading Canon Tristram's "Fauna of Palestine" appears beneath sub-section Italy—the compiler seems doomed to disaster in his relations with the clergy. In one or two cases where comprehensive titles occur, a process of dismemberment has crept in. For example: Romanes' "Jelly-Fish, Star-Fish, and Sea-Urchins" is to be found under Star-Fish and Sea-Urchins, with the title mutilated beyond recognition, but not at all under either Jelly-Fish, Medusa, or Echinoderm; Scott Russell's "Wave of Translation in the Oceans of Water, Air, and Ether," to which allusion has already been made, occurs, also with a misquoted title, under Water, but under neither Ether nor Air and Atmosphere.

Such are the results of an attempt to gauge the working capacity of the "Index" mainly from a single stand-point. I leave other specialists to inquire for themselves. It has been said that this "work proves the ability and industry of its compiler, and that the Trustees are anxious to make the treasures of the great library a success." Granted the good intentions of the governing body and the industry of the compiler; of the rest the reader must judge for himself—I refrain from further comment thereon. It cannot, however, be admitted that the compiler has done his best; errors cannot be avoided where non-technical hands are applied to technical work, but slovenliness is ever intolerable. I submit that a distribution of labour is demanded for the success of the next essay of the kind.

JUSTITIA

The Origin of Species

IN a recent issue of NATURE (Nov. 25, p. 77) Mr. Catchpool writes:—"Is it, or is it not, the fact that allied species, which are confined each to a particular island, prove, when brought together, far less frequently infertile than species, equally dissimilar, which had lived in the same district, might be expected to prove? On the answer to this question depends, as far as I can see, the fate of the theory of physiological selection. Can no one answer it?"

This is a question which has arisen out of the theory of physiological selection itself, and, as Mr. Catchpool was the first to propound that theory, I am afraid he will find that no one as yet is able to answer his question. But it may interest some of your readers to know that I have collected a considerable body of facts tending to show that there is a correlation between fertility of allied species and the fact of their living on isolated areas, as well as another correlation between sterility of allied species and the fact of their living on continuous areas. But it seemed to me undesirable to publish these facts until very largely augmented; and, finding that no observations had been expressly made upon the subject, I read my paper before the Linnean Society for the purpose of inducing naturalists in different parts of the world to try experiments on the fertility of nearly allied species inhabiting isolated areas, as well as to test for degrees of sterility between natural varieties and parent forms on continuous areas. Meanwhile I am myself trying experiments on the mutual fertility of isolated species, as well as upon the sterility of natural varieties with parent forms. Where birds and mammals are concerned, I am using the numberless islands of all sizes on the west coast of Scotland, which are admirably suited to the purpose. Any of your readers in any parts of the world who are acquainted with well-marked natural varieties of birds or mammals which (together with their parent forms) would be likely to thrive on these islands, would greatly oblige me by communicating suggestions.

I may take this opportunity of also requesting any of your readers who may have further remarks or criticisms to make on the theory of physiological selection not to delay their publication. For it is surely desirable that discussion of the subject "on the high *priori* road" should come to an end. Until a large number of experiments shall have been made, any definite judgment upon the theory must be either biassed or premature; and therefore the only influence that can now be exercised by adverse criticism is that of discouraging the work of verification. On this account, and on this account alone, is it worth one's while to answer such criticism. Hitherto I have waited till it should come to an end, and withdrawn the answer previously referred to in these columns as having been in type for the *Fortnightly Review*. When it has come to an end, I will furnish a general reply in the *Nineteenth Century*, and shall then hope to show that whatever "fate" may be in store for the theory at the hands of Nature, at all events it is certain that it has been in no way affected by the assault of naturalists.

George J. Romanes

Heredity in Abnormal-Toed Cats

The calculation made by Mr. J. H. Hodd in last week's Nature (p. 53) of the numerical proportion of the sexes of Mr. Poulton's race of extra-toed cats, in relation to the recurrence of the abnormity, is very interesting as an inferrable deduction from the premises of Mr. Poulton's elaborate tabulation of his observations; but it is, I think, doubtful whether it is not misleading as a generalisation from the facts collected by him. A conclusion arrived at by means of a mathematical method is too absolute an inference, and not necessarily reliable, when applied to purely biological cases, on account of the numerous intervening factors (perhaps mostly unknown, but yet of importance) which are incapable of being appreciated within such an estimate, and which may, in consequence, invalidate the main point under consideration. This appears to be the case on the present occasion; for Mr. Poulton mentions, in describing the kittens of $VIII^5$ (p. 39), that by far the most highly specialised development of the abnormity he has observed, throughout the entire race, was attained in a *male*—$VIII^5$ iv. Considering that the large majority of individuals possessing the character are of the ♀ sex, as pointed out by Mr. Hodd, this fact is really very striking. But, at the same time, if the point alluded to by Mr. Hodd were considered as amounting to a principle, we should naturally be led to infer that the abnormity might become equivalent to a secondary sexual character, which is so improbable that it scarcely bears suggestion. Besides, it is necessary to bear in mind that all the observations carried on as yet by Mr. Poulton have dealt *with the ♀ influence alone;* and it may be accounted for by the very reason that all the ♂ s have been carefully eliminated from exercising any influence on the race, that the predominant effect, *numerically*, is on the ♀ side; while it is most probable that if an abnormal ♂ were selected (say, the individual just referred to) as a starting-point for experiment with normal ♀ s, the result would exhibit a general tendency towards superior persistence of the character operating with greater potency amongst the males than the females. It would be very interesting to experiment in this manner under the isolation happily promised in the Madeiran Islands.

Mr. Hodd's statistical statement is, doubtless, correct in the main, under the restricted provision just suggested, only one must not attach too great importance to it. The preponderance in number of the ♀ s over ♂ s is, indeed, still more noticeable when the ratio of each sex to the total number of the thirty-six cats is considered. Thus it appears that of twelve ♂ s $13\frac{8}{9}$ per cent. are normal, and only $19\frac{4}{9}$ per cent. abnormal; whilst of the twenty-four ♀ s $19\frac{4}{9}$ per cent. are normal, as many as $47\frac{2}{9}$ per cent. are abnormal. It is perhaps a little premature to place entire reliance upon so small a number, but it will prove interesting to compare the statistics brought out in Mr. Hodd's letter with a larger number in time to come.

In considering such a close and carefully detailed analysis as that presented by Mr. Poulton, it is of no little interest to find, on referring to that wealth of facts and principles, "The Descent of Man," that these results are in complete accord with, and confirm the laws of inheritance formulated by Darwin, if the strictures imposed by him, as if in anticipation of future observations, are duly regarded; and as his remarks apply to the present subject very directly,—although bearing more especially upon sexual selection in general,—I cannot do better than quote some of the more pithy:—"Why certain characters should be inherited by both sexes, and other characters by one sex alone, namely by that sex in which the character first appeared, is in most cases quite unknown. We cannot even conjecture why with certain sub-breeds of the pigeon, black striæ, though transmitted through the female, should be developed in the male alone, whilst every other character is equally transferred to both sexes; why, again, with cats, the tortoiseshell colour should, with rare exceptions, be developed in the female alone" ("Descent," 2nd ed., p. 232). It is curious that the cats under observation happen to be tabby-tortoiseshell, and the remark made by Darwin (p. 230), that "as a rule it is the females alone in cats which are tortoiseshell, the corresponding colour in the males being rusty red," fully obtains in the present case, since the ♂ s are, unless tabby, sandy-coloured, but never tortoiseshell. It is furthermore important to notice that the sandy individuals have the supernumerary digits as fully developed as any of the ♀ s in the same litter.

Darwin's explanation of the persistence of abnormal characters is on the lines of the theory of pangenesis, as follows:—

"It is in itself probable that any character appearing at an early age would tend to be inherited equally by both sexes, for the sexes do not differ much in constitution before the power of reproduction is gained. On the other hand, after this power has been gained, and the sexes have come to differ in constitution, the gemmules (if I may again use the language of pangenesis), which are cast off from each varying part of the one sex, would be much more likely to possess the proper affinities for uniting with the tissues of the same sex, and thus becoming developed, than in the other sex" (p. 232). On p. 237 we find the further remark:—"The presence of supernumerary digits, and the absence of certain phalanges, must be determined at an early embryonic period, ... yet these peculiarities, and other similar ones, are often limited in their transmission to one sex: so that the rule that characters developed at an early period tend to be transmitted to both sexes here wholly fails." [1]

And, in conclusion:—"Characters of the parents often, or even generally, tend to become developed in the offspring of the same sex, at the same age, ... in which they first appeared in the parents. *But these rules, owing to unknown causes, are far from being fixed.* Hence, during the modification of a species, the successive changes may readily be transmitted in different ways; some to one sex, and some to both; some to the offspring at one age, and some to the offspring at all ages. Not only are the laws of inheritance extremely complex, but so are the causes which induce and govern variability" (p. 240).

It is quite remarkable, though it is not at all surprising, how closely Mr. Poulton's facts fit into these deductions of Darwin's, drawn, as they were, from such few instances that they seem to be little less than preconceived ideas.

But, as it may be due to a one-sided influence in special

[1] This is a point which perhaps requires further evidence.

cases that an effect is found to have clung with so much persistence to one sex, I am inclined to believe that, upon the experiment being made as I have suggested, that the other sex will produce similar results in regard to the numerical proportion of the sexes, and a strong point in favour of this opinion lies in the fact that, as I have myself seen, a sandy-coloured ♂ kitten, apparently bearing the stamp of the normal ♂ parent, was found to bear the development of the supernumerary digits in a marked degree. Algebraic Notation of Kinship

WITH reference to Mr. Davison's letter in NATURE (vol. xxxiv. p. 571), I wish to point out that the subject of algebraic notation, not only for kinship, but for kinship and affinity, has been pretty fully discussed in several papers which I contributed to the Royal Society of Edinburgh, and especially in a paper entitled "Analysis of Relationships of Consanguinity and Affinity," which, at the request of Mr. Galton and Dr. Tylor, I contributed to the Anthropological Institute (*Journal* of the Anthropological Institute, August 1882). Some idea of the nature of that paper may be got from a statement of the several tables which are appended to it. Table I. gives the notation for the general relations of the first five orders, states the general and singular meaning of each, and classifies them according to index, sign, and grade. Table II. shows how these general relationships are divided into ultimate species. Table III. gives all the possible relationships of a man to a woman, and of a woman to a man, within the first five orders; and such relationships as exclude marriage according to the laws of England are marked with an asterisk. Table IV. gives the consanguineous relationships of the first five orders grouped in lines and species, the agnatic system being formed by the extreme terms on the left, and the uterine system by the extreme terms on the right. Table V. gives strict definitions of the English terms of relationship.

Besides the algebraic notation, I also developed a graphical notation. In the paper referred to, I apply the graphical notation to show the descent of property according to the English law.

Prof. Jevons took much interest in these papers, and it was his intention to give the elements of the analysis in a new chapter of his "Studies in Deductive Logic," but death snatched him from us in the midst of his scientific labours.

University of Texas, Rustin, Texas, November 15

Seismometry

IN the last number of NATURE (p. 75) there appears a letter by Prof. J. A. Ewing, referring to a note in a previous number (p. 36), apparently a summary of a communication from Prof. Milne. As I have some interest in this question, and have reason to believe from remarks made in a letter lately received from Prof. Milne that the matters referred to by Prof. Ewing cannot be those to which Prof. Milne referred, I should be glad if the original communication could be published.

Prof. Ewing's letter and indeed several of his recent publications, including the description of his instruments in NATURE, are decidedly calculated to mislead those not familiar with the seismological work which has been done in Japan. For example, he says, or leads one to infer, that he introduced horizontal pendulums in seismology: now that is not the case. It is needless for me to say that horizontal pendulums have long been known as a means of obtaining nearly neutral equilibrium; and in particular, with reference to Japan, they are referred to by Prof. Milne on page 25 of vol. i. part 1 of the *Trans. Seis. Soc. Japan*, in a paper which was read in Prof. Ewing's presence several months before Prof. Ewing's instrument was heard of. What Prof. Ewing did introduce was a particular form of horizontal pendulum, very particularly described by him in some of his early papers, as involving a "new principle" (now apparently abandoned by him), and he used two such pendulums to write two components of the earth's motion on a *continuously* moving plate. Records on moving surfaces were not new then, even in Japan, as they are referred to in papers published by other investigators before Prof. Ewing arrived in the country, but there was this difference in these older methods, that the plates were automatically started by the earthquake; and Prof. Ewing, after his experience, has now adopted this plan.

Prof. Ewing mentions also in his letter that his apparatus writes three components of the motion, but he does not say that the most difficult of the three—namely, the vertical component—is written by an instrument which I introduced and described before the Seismological Society of Japan, first in May 1880, and afterwards in a modified form in April 1881. Prof. Ewing's instrument is professedly, as his first description (*Trans. Seis. Soc. Japan*, vol. iii.) clearly shows, a modification of my second form, and is, what he seems persistently to have shut his eyes to, almost identical with my early form.

As to Prof. Ewing's statement in the last sentence of his letter that "there is nothing better to take their place," we can hardly be expected to take *his* judgment on this point.

THOMAS GRAY

[Nothing essential was omitted from Prof. Milne's letter.—ED.]

Botanical Lecture Experiment

THE following simple lecture-experiment may interest teachers of botany. It is described by Georg Klebs in his paper "Ueber d. Organisation d. Gallerte bei einigen Algen u. Flagellaten," published in the most recent part of *Unters. a. d. bot. Inst. z. Tubingen*. A description of the experiment I give in Klebs's words, translated:—"It is easy to demonstrate, by addition of a watery solution of phenolphtalein, that Algæ make the water in which they live alkaline when they are fixing carbon in light. In proportion as the fixation of carbon proceeds, the water gradually assumes a deep red tinge, which gradually disappears when light is excluded." The explanation given is:—"The Alga takes up not only the CO_2 absorbed in the water, but also in part that which is in combination in acid carbonates, in consequence of which alkaline combinations arise; in darkness, owing to respiration, the reverse process takes place."

I have a vessel with water containing phenolphtalein in which Cladophora has grown for nearly three weeks, and there is daily a reddening of the water, its rapidity being determined by the brightness of the day; during the night the colour disappears.

BAYLEY BALFOUR

A Lecture Experiment on the Expansion of Solids by Heat

MR. MADAN'S description of a device for showing that metals and solids expand when exposed to heat is very interesting, especially as such an arrangement, but with important modifications, is capable of giving very excellent scientific results, results which are only surpassed by M. Fizeau's method. One necessary alteration is the substitution of a spring-pressure for the weight on the strip of metal. This and other points will be made quite clear by a perusal of a short description contained in my paper, "A Strain-Indicator for Use at Sea," read before the Institution of Naval Architects. The numerous tables and diagrams there given would, I am afraid, hardly interest your readers, but the repeated experiments in Table I. would be a subject of interest, as they show how well the experiments agree amongst themselves. The errors, though small, are due, in my opinion, not only to the difficulty of reading the dial (each unit being equal to about half an inch, and the second decimal therefore about 1/200 inch), but also to the difficulty of reading the exact position of the weight on the steel-yard of the testing-machine. Far more accurate results are obtained when, instead of a jockey weight being run out, small weights are added one by one.

You will also notice that the instrument gives very good records on paper (see launching strain diagrams and railway bridge diagrams), and in this shape it could, I think, be used with advantage for recording changes of temperature.

Strawberry Hill, Middlesex, December 2

Meteors and Auroras

IN the *Proceedings* of the Paris Academy of Sciences published in NATURE for November 4, at p. 23, a relation between showers of shooting-stars and auroras is noted. In this vicinity on April 14, May 8, July 27, and November 2, very fine auroras were visible, and upon each occasion shooting-stars of unusual brilliancy were observed in the northern heavens whilst the aurora was at its height. THE GUTHRIE MEMORIAL FUND

A COMMITTEE has been formed, under the presidency of Prof. Huxley, to raise a memorial fund in honour of the late Prof. Guthrie, F.R.S. Prof. Guthrie endeared himself to a large circle of friends by his simple character and wide sympathies. Unfortunately, as his time was exclusively devoted to teaching and to scientific research, the provision for his family is far from adequate. A slender income is furnished for his widow by a policy of insurance settled upon herself, but this will not enable her to provide for the education and maintenance of her step-children. The ages of the children dependent upon her are twelve, fourteen, and seventeen years respectively, and their case is the more sad because, until a late period of his life, Dr. Guthrie had every reason to be satisfied that they were sufficiently provided for.

Under these circumstances it will be felt by all who value his memory, as well as by those who only knew him through his scientific labours, that any sum which is gathered as a memorial of his life must necessarily be devoted to placing his children as nearly as may be possible in the position they would have occupied but for his untimely death.

Subscriptions may be sent to the Honorary Treasurer, Major Macgregor, R.E., Science Schools, South Kensington Museum, London, S.W.; or to the Honorary Secretary of the fund, Mr. C. Vernon Boys, at the same address. Cheques to be crossed "Messrs. Cox and Co."

In addition to the gentlemen named above, the Executive Committee consists of Capt. Abney, Prof. W. G. Adams, Prof. Roberts-Austen, Walter Besant, Prof. G. Carey Foster, Dr. J. H. Gladstone, W. J. Harrison, J. Power Hicks, Prof. J. W. Judd, Prof. A. W. Reinold, and Prof. Balfour Stewart; besides whom there is a General Committee, comprising Prof. W. E. Ayrton, Shelford Bidwell, Walter Bailey, T. Lauder Brunton, W. H. M. Christie, Prof. Clifton, Conrad Cooke, Prof. Crookes, Warren De La Rue, Prof. Dewar, Colonel Donnelly, General Festing, Prof. G. Forbes, Prof. Fuller, R. T. Glazebrook, Prof. Goodeve, Dr. Hopkinson, J. Norman Lockyer, Sir John Lubbock, Bart., Prof. MacLeod, Prof. J. Perry, Prof. Poynting, Prof. Rücker, Dr. W. J. Russell, Prof. W. A. Tilden, Prof. S. P. Thompson, Prof. Thorpe, and Dr. Alder Wright.

It is satisfactory to hear that already a considerable number of subscriptions have been received, but it is hoped that when the necessity for the existence of such a fund shall become better known there may be a large increase in the number.

VOLCANIC ERUPTION IN NIUA-FU, FRIENDLY ISLANDS

SIR J. H. LEFROY has forwarded to me a small packet of volcanic dust, together with an extract from a letter written by Mr. Coutts Trotter, F.R.G.S., and has requested me to examine the former and append my remarks upon it to the more important parts of Mr. Trotter's letter. This document is dated on September 24, 1886, "on board the ss. *Suva*, a few miles south of the Island of Niua-foou" (or Niua-fu, one of the Friendly Islands). After speaking of an expedition to Fiji, Mr. Trotter proceeds:—

"Meanwhile I got into a little steamer to visit the windward island of the group, and was persuaded to come on in her to Tonga. There I found that news had just come of an awful volcanic eruption in the Island of Niua-foou above mentioned, and my steamer was chartered to go and make inquiries and give relief. . . . We started at once, and arrived off the island before dark yesterday. No trace of fire or smoke, and I was much chaffed for my 'disappointment.' But on landing this morning we ound the damage done was substantial enough, an eruption of dust and stones and water having gone on for eighteen days, and two-thirds of the island smothered or greatly injured. The island is some forty or fifty miles round, all volcanic, no beach anywhere, and landing difficult, and a lake of brackish-bitter water occupying perhaps a fourth or more of its extent. There are at all events three small islands in the lake, one with a lake in its centre. I suspect this lake is the remains of the crater and eruption to which the existence of the island is due, later eruptions being cause for the small island craters. The present eruption began apparently near one end of the lake. I saw three or four craters there—one covered with a green sulphurous scum; and another, just beyond it, which I could not in the time I had actually visit, very deep, and full (a friend tells me) of mud and water. Near it is a little rounded mountain of 'earth,' some 200 feet high, formed by the present eruption, and projecting far into the lake; at the other end of the lake is a fresh accumulation, as I was told, of pumice, but it looked to me from where I stood more like an accumulation of black sand. The whole island has been in a disturbed state for some three months and a half, the dates of the principal disturbances coinciding remarkably with those which are going on in other parts of the world—earthquakes on June 8 and 11, which I think are the dates of the first New Zealand outbreaks,[1] again on August 12, ditto. This of course is not wonderful, but the final catastrophe here took place on August 31, which we understand was the exact date of the recent American earthquake.[2] It was preceded for twenty-four hours by earthquakes, . . . and went on for ten days, I am told, without intermission, then two days quiet interval, then going on again for nearly a week—terrific thunder and lightning for twenty-four hours incessantly. The column of steam rose, they say, several thousand feet, anyhow immensely higher than a hill 7600 feet high, which I ascended, and whence I had a bird's-eye view of the lake and crater. Showers of stone accompanied it; these fortunately fell straight, or nearly straight, back. They were red-hot, with masses of dust attached, and as they fell left the dust behind, which produced the effect of a fiery tail. The great mischief was done by the dust, which, as the wind shifted, carried destruction in every direction. In one village which I entered, the shower only lasted an hour and a half, but the ground was deeply covered, the blades of grass even now only beginning to peep through, and every coco-palm ruined for the present, the branches hanging withered and almost perpendicular, and the young central shoot sticking out by itself. If they get rain, the trees will recover and bear again in three years, but otherwise are likely to die. But in other districts the houses are buried, and along the coast large extents of forest, scrub, or bush, and, what is more immediately serious, the yam beds. They have just been planted, and any that were above ground will be killed, even if the latest planted may push through and flourish. Wonderful to say, no one was killed, although many very old people have died since from fear and exhaustion. They all betook themselves to the upper parts of the island for safety, and perhaps with reason, for the last two volcanic outbursts both took place on the coast-country near the shore. These (respectively nineteen and forty years ago) were both lava eruptions. I saw the craters and the lava-streams from them down to the sea on the west coast as we steamed along to-day; the lava of the earliest being hardly invaded yet by vegetation—not a blade of green on the later, which runs far out into the sea, like the rough substratum for a big embankment or breakwater. According to native tradition, the last eruption of a kind similar to the present took place from very nearly the same spot in the lake seventy-two years ago, the old people having childish recollections yet. The

[1] The first outbreak was early on the morning of June 10. See NATURE, vol. xxxiv. p. 301.

[2] The principal shock was on Tuesday night, August 31. See NATURE, vol. xxxiv. p. 470, and vol. xxxv. p. 31.

lake is a great depth, so that this hill of 200 feet or more rising from the bottom represents a vast amount of solid matter, to say nothing of the thick deposits of dust all over the island. The lake was still bubbling in places, and things are by no means settled down yet. At Vavau, where we touched two days ago, they had just had a very severe earthquake, and shocks are still going on at Niuafoou (vertical, *I was told*, but my informant's wits were much shaken by recent events) daily on the level ground near our landing-place, from which it is inferred that the danger is not over. Strong gases too are perceptible rising from the ground near the coast, which is always where they apprehend most danger, and an outburst of lava. I suppose the solid matter coming up through the deep lake is pulverised into the (to life) comparatively harmless dust. During the earthquake of August 12, the captain of a ship at anchor found that, whereas he had paid out twenty fathoms of chain over-night, he had only eight fathoms under him in the morning. I never saw such big coco-nuts anywhere, though the trees are not exceptionally big, indeed there seem to be no very fine or old trees of any kind on the island, which favours the theory of a modern origin, for the soil is very fertile. The name means New Niua, the Old Niua being probably the neighbouring Keppel Island or Niua-tobu-dabu. I wish I could give you a better or fuller and more interesting account of the whole affair, but the visit was a very hurried one, and, in fact, I had not more than two hours on shore. Still it may interest you, as it is written on the very spot: no other account is likely to reach England. I send a pinch of 'sand' from the crater. "C. T."

This "sand" or "dust" is a very dark-brown—almost black—colour. When examined with a lens it seems composed mainly of fragments of glass, and has a slightly speckled aspect; owing to the mixture of lighter and darker fragments; one or two glassy-white fragments may also be noted. When some of the dust is placed under the microscope, it is seen to consist almost wholly of fragments—some rudely polygonal in shape, others flattish chips—of a brown glass; the former being the commoner. The majority of the bits vary from about ·01 inch to ·03 inch in diameter, and the latter measurement is but rarely exceeded. Minute chips are also present, but they do not form at all an important constituent in the mass. A conspicuous characteristic is the (apparently) entire absence of the tiny pellets of "cindery" scoria, so frequent a constituent of volcanic dust, and of the fine pulverulent material, the presence of which commonly makes it needful to mount the dust on a slide before it can be properly studied. I have found no difficulty in examining this Niua-fu dust, and even the finer chips—often less than ·001 inch in diameter—by simply spreading it over a sheet of glass. The glass fragments, even when very minute, have a tinge of brown: when about ·01 inch in thickness, they are fairly translucent, and a rich olive-brown in colour; but as they approach ·03 inch in thickness they become opaque, light only passing through the thinner edges. Small cavities, spherical, or egg-shaped, are not infrequent, but the glass is remarkably free from microlithic inclosures. No granulation of the colouring-matter is perceptible, as a rule, with a magnification of 150 diameters; opacite dust and trichites (especially the latter) are very rare; and of other microlithic inclosures I have only seen an occasional lath-shaped crystallite (? feldspar). I have not identified among the fragments either biotite, augite, or hornblende; so that if any of these minerals are present they must be very rare. The clear glassy fragments mentioned above are feldspar—probably labradorite. They do not in number exceed about 2 or 3 per cent. of the whole. Many of the flatter brown-glass fragments exhibit ropy folds or the remains of a cellular structure, evidencing that they are due to the destruction of a very vesicular glass, while the more solid polygonal fragments may be the detritus of the thicker parts of the same or of a more uniform glass. The strong brown colour of the fragments reminds me of specimens of the more glassy lavas of the Sandwich Islands in my collection; and like them I should, from microscopic examination, consider the rock a basalt-glass (tachylyte) with a silica percentage, which was probably above rather than below 50. This view accords, I find, with Cohen's statement concerning the lava of Niua-fu, which, judging from his description, is very similar to that above described (*Neues Jahrb. für Min.* 1880, vol. ii. pp. 36 and 41); he says that it is almost identical in composition with the "basalt-obsidians" (*i.e.* tachylytes) of the Sandwich Islands. It contains 50·74 of silica; their analyses show from 50·82 to 53·81.

While the above was passing through the press, I received from my friend Dr. S. Rideal a determination of the specific gravity of the volcanic material (powdered to get rid of cavities). The specific gravity is 2·726. As the feldspar is included, and it is slightly the lighter, the specific gravity of the glass itself must be a little higher, about 2·73. Hence we need not hesitate to call it a tachylyte. The average of six Sandwich Island glasses is 2·71 (see Judd, *Q. J. G. S.*, xxxix. 444).

T. G. BONNEY

FOURTH ANNUAL REPORT OF THE FISHERY BOARD FOR SCOTLAND

THE Report of the Fishery Board for Scotland increases each year, not only in size, but in interest for the general public, as well as for those readers whom it specially concerns; and, unlike ordinary Blue-books, its pages are to a large extent devoted to scientific papers which appeal to many not directly concerned with the fishery industry.

The herring-fisheries continue to be most productive. A very striking feature of the summer herring-fishery of 1885 is, that many in-shore grounds, where herrings were previously found in great abundance, but which had recently been all but deserted, were restored to their former fertility. The increase of the herring-fishery in the Shetland district, which now ranks as the most important in the country, still continues, greatly to the improvement of the condition both of the people and of their boats. The fish are of finer quality than those taken on other parts of the east coast. The takes of other sea fish and salmon were also very large. The gross total estimated value of the sea and salmon-fisheries for Scotland was 2,859,822*l*. 15*s*. The Board have already expressed their regret that so many tons of sprats are annually used as manure. Could they be transmitted to populous districts at a reasonable rate, they would be a cheap and valuable addition to the food-supply, or, where this was impracticable, preserved as anchovies as in Norway, or as sardines as in Canada. The importance of utilising the by-products of the fisheries is now widely recognised. Papers by Dr. Stirling and Mr. Haliburton give an account of certain economical products obtained from fish, and experiments are being made on a fairly large scale by Mr. Sahlström at Aberdeen, which may, it is hoped, lead to some practical results. Investigations on whitebait by Prof. Ewart and Mr. Matthews showed it to consist almost entirely, and at all seasons, of young sprats and young herrings, varying according to the season of the year and the place of capture. It might, therefore, be advantageous for the Firth of Forth and other in-shore waters to send supplies of whitebait to the English markets.

The Scientific Committee of the Board had the assistance of Mr. Brook, Prof. Stirling, and Mr. Duncan Matthews, of Aberdeen; Prof. McIntosh, of St. Andrews; Prof. Greenfield and Dr. Gibson, University of Edinburgh; the Rev. A. M. Norman, D.C.L. of Durham; and Mr. Haliburton, of University College, London. Though the Marine Laboratories at Tarbert and St. Andrews admitted of several important inquiries being initiated, the Board is still greatly hampered for want of proper boats, and throughout the year the limited amount of dredging and field-work done was rendered possible by boats supplied by Prof. Ewart. It is to be hoped that arrangements will be made by the Admiralty, which will admit of the superintending vessels undertaking a complete survey of the spawning-banks and assisting in work of a like nature when required. A small steamer has already been provided for trawling experiments and other work on the east coast. At the Rothesay Aquarium the spawning of the cod was studied by Prof. Ewart and Mr. Brook, who generally confirmed the observations of Sars, and gained further information as to the natural and artificial fertilisation of the eggs, and their buoyancy before and after fertilisation in different kinds of water. The appendix contains part ii. of a paper by Mr. Brook on the development of the herring. Experiments made in artificial fertilisation of herring eggs appear to justify the following conclusions:—

(1) The ova retain their vitality, and are capable of being fertilised from forty to forty-eight hours after the female is dead. In the experiments performed, forty-eight hours seems to be a little outside the limit at which the eggs are capable of being fertilised, but it is probable that temperature may have an influence on the vitality of the ova. (2) The spermatozoa do not retain their vitality for nearly so long a period. Three hours appears to be the limit indicated by the above experiments. (3) The egg capsule never separates from the yolk excepting under the influence of spermatozoa. It would appear that when the ova and spermatozoa have partly lost their vitality a partial separation of the egg membrane from the yolk may take place, although the ovum is not truly fertilised. Experiments proved conclusively that the egg capsule is not permeable to water until after it has been penetrated by spermatozoa. (4) The egg membrane is covered with a viscous secretion when the ovum leaves the oviduct, which serves for the attachment of the ovum. This viscous layer gradually hardens in sea-water. Active spermatozoa are able to penetrate this layer some hours after it has set, but this power appears to be confined to the first twenty-four hours after deposition. (5) There is no collection of germinal protoplasm at the surface of the yolk in the ripe ovarian ovum, nor is a germinal disk ever found so long as an ovum remains unfertilised. The formation of the germinal disk cannot be made out in living ova, and its true nature can only be determined from a study of sections. Investigations on the formation of the blastoderm, and examination of a large number of sections, lead to the conclusion that the animal pole of the ovum gives rise to the ectoderm. In many forms the animal pole at the time of the formation of the segmentation cavity consists only of true archeblast cells. In the herring, and probably some other forms, the animal pole receives an addition of cells from the parablast prior to the formation of the segmentation cavity. The primitive hypoblast, which is almost entirely derived from the parablast (*i.e.* from the vegetative pole), gives rise to the mesoderm, and the secondary hypoblast (endoderm) remains as a single row of cells in connection with the parablast.

If these conclusions are correct, the similarity between the development of teleosteans and amphibians (*Rana*) cannot fail to be noted. The derivatives of the animal and vegetative poles are in both cases practically identical. The secondary segmentation (budding) in the parablast of teleosteans must then be regarded as the necessary consequence of the relative distribution of protoplasm and yolk in the vegetative pole. The primitive hypoblast, as here described for the herring, is precisely homologous with that of Amphioxus. In both cases the primitive layer gives rise to mesoderm, notochord, and true endoderm. The position here brought forward is one advocated by Mr. Brook over a year ago, but from the nature of the material then at his disposal he failed to observe the details of the process. Quite recently, Dr. Ruckert, who has been studying the behaviour of the parablast in Elasmobranchs, has come to conclusions practically identical with those here advocated for Teleosteans.

The question, "Are herring ova likely to develop normally on the deep off-shore fishing-banks?" is discussed by Prof. Ewart in a way which shows that the Board aims at practical results as much as mere scientific investigations.

Until comparatively recent years nearly all the herring taken in summer were captured by small boats within a few miles from the shore. In 1852, *e.g.*, immense herring shoals reached the Moray Firth to spawn on the Guillam and other in-shore banks. Since 1852 the fishing boats have greatly increased in size, and owing to the introduction of cotton nets, each boat has added greatly to its catching power.

As the boats have increased in size and sea-worthiness, the fishermen have proceeded farther and farther to sea in search of the herring shoals, and now the greater number of the herring are taken from forty to sixty miles from the coast. It is often alleged that it was owing to the herring deserting the in-shore grounds that the fishermen proceeded to sea in search of the shoals, and also that it is because the fishermen disturb and break up the shoals early in the season that they no longer or seldom visit their old spawning-grounds. There is no doubt that during the last fifteen years comparatively few herring have been captured during the summer over the in-shore banks of the Moray Firth; but whether this is the result (as is alleged) of the fishermen intercepting and breaking up the shoals before they have had time to reach the in-shore ground it is impossible to say. It is, however, a question of great interest, and one which could in all probability be easily settled. If the fishermen were to refrain from fishing for one year in the various districts along the east coast until the fish had reached maturity, this problem would most likely be solved. In all probability the herring would be found as abundantly as in former years in the in-shore waters, and the fish captured would be larger and riper than those taken early in the fishing-season of former years from the corresponding shoals.

That the takes during recent years have consisted chiefly of small fish (so-called maties), will be evident by a reference to Reports of the Fishery Board. It is generally admitted that the great depression of the fishery industry which now prevails would, to a great extent, have been prevented if half of the small herring (the maties) had been left in the sea. Many of those who account for fewer herring being captured in-shore, by saying it is impossible for them to run the gauntlet of the thousands of nets that are night after night drifting across their path, assert that the eggs are incapable of developing in deep water, and that in course of time the off-shore shoals will diminish or disappear. Of this there is in the meantime no evidence. As a matter of fact, for all we know there may have been immense shoals of herring spawning on the banks which lie at a distance of from thirty to sixty miles off the Scottish coast for centuries.

The existence and continuance of off-shore shoals will, to a great extent, depend on whether the herring are able to reproduce themselves without visiting the in-shore spawning-banks, and the success of the herring industry will depend on whether the herring shoals, which are invaded annually by our fishing fleet, continue to spawn sufficiently near the coast to render their capture a profitable enterprise for our fishermen. For this it is necessary to have large shoals moving in limited areas, and these are only found on the east coast during the winter and summer spawning-seasons. If herring ova are capable of hatching in deep water (say from 60 to 100 fathoms) it may be taken for granted that any of the many gravel-coated banks of the North Sea may serve as spawning-beds. The North Sea is remarkably shallow, there being only one small area near our shores (generally known as the "Pot," and lying two to five miles off Fraserburgh), where a depth of 100 fathoms is reached. The most certain way of proving whether herring ova hatch or not in deep water would be to dredge herring spawn from one of the off-shore banks in an advanced stage of development; but, after several unsuccessful attempts to do this, it occurred to Prof. Ewart that the question might be practically settled by depositing fertilised eggs in specially constructed hatching-boxes in deep water. This was done in the "Pot," but without result, as a storm swept away all traces either of buoys or boxes. The Moray Firth being in many respects unsuitable for this experiment, Prof. Ewart turned his attention to the West Coast, and found a comparatively sheltered spot in Loch Fyne, with a depth of 104 fathoms. To insure success, a small tank was constructed of thick slate slabs firmly bound together by iron rods. The tank, though only about 20 inches square, weighed nearly 2 cwts. In the top and in two sides of this tank small windows were made about 6 inches square. Each window was carefully fitted with a teak frame, across which a single layer of horsehair cloth was stretched. These windows admitted a sufficient current of water to pass through the tank. All the necessary preparations having been made for depositing the tank during last autumn. Mr. Brook, who was engaged at the Fishery Board Tarbert Station during the autumn, undertook to obtain eggs and superintend the sinking of the tank in the 100-fathom water. Eggs were obtained on September 11 from herring caught in Kilbrannan Sound in water varying from 8 to 12 fathoms. All the eggs were placed at first in the laboratory in water which had an average temperature of 54° F. Most of the eggs kept in the laboratory hatched out on the 19th, while others only hatched on the 24th, thirteen days after fertilisation. On the 16th, one of the glass plates, coated with eggs, was introduced into the tank above mentioned, which was immediately conveyed to the middle of the channel, and deposited in 98 fathoms water, about three miles off Tarbert. The surface temperature was 54° F., the bottom temperature was 49° F. The bottom around the tank was chiefly composed of mud. On the 24th—*i.e.* thirteen days after fertilisation, and eight days after the eggs were deposited in 98 fathoms water—the tank was raised. On examining the glass plate, it was found a number of the eggs in the centre had been destroyed by a fine coating of mud, which had entered through the hair-cloth screen, while those near the margins contained vigorous embryos almost ready to hatch; in a few cases hatching had taken place. The average bottom temperature while the eggs were deposited was 49°·3 F.; the average surface temperature, 54° F.,—the difference being 4°·7. The difference of 4°·7 during the eight days which the eggs were deposited delayed hatching for about five days. This experiment clearly shows that the only difference between the hatching of herring ova in deep and shallow water is one of time; hence we are safe in concluding that if herring deposit their eggs on suitable ground, in any depth of water not exceeding 100 fathoms, they will undergo development. It is conceivable, however, that the depth of the water in which the eggs are deposited may have some influence on the time of spawning—in other words, on the fishing-season; and the immature condition of the fish caught in August during recent years may to some extent be accounted for in this way. If the herring which formerly spawned on the in-shore banks of the Moray Firth in from 10 to 20 fathoms water now spawn off-shore in from 40 to 60 fathoms water, the hatching will be delayed for several days, and maturity will not be reached as early as formerly. This is an argument in favour of beginning the herring-fishing later in the season than at present. It may be objected that the fry, if hatched out in deep water, would never succeed in reaching the surface; and supposing that they could, the necessary food might not be found forty to sixty miles from shore. Observations, however, show that the young herring are likely to have little difficulty in ascending 200 fathoms before the yolk-sac is exhausted, and that though no one is yet well acquainted with the food of the fry, there can be no doubt about the richness of the surface fauna beyond even the fifty-mile line.

In the Report for 1883, Prof. Ewart called attention to the fact that the German Commission had arrived at the conclusion that the Baltic herring differed sufficiently from the North Sea herring to be worthy of being considered a special variety. It has long been held by fishermen and others that each district has its own peculiar variety. From some 500 specimens examined in 1883, no evidence of the existence of such varieties was found. In order to settle this question finally, Mr. Duncan Matthews has been examining, for a considerable time, samples of the herring captured around the Scottish coast, and now communicates an important paper on this subject. The method of investigation adopted was to take accurate measurements of the length of the head, and of the caudal, dorsal, and anal fins, to note the position of the fins on the body, &c., and, by a comparison of these data with the length of the body, to ascertain the amount of their actual variation, and especially whether these variations were so constant in the herrings of any one or more localities or seasons as to indicate a distinction of races. From this inquiry it seems that there are as large herring now as there were some generations ago, and that, although each district yields large herring, the north-east coast has a slight advantage in this respect over the south-east and west coasts. A table giving the size, &c., of the largest fish examined includes representatives from every fishery district, and shows that there is no practical difference in size between the male and female, nor in the numbers of each of these which were taken. The winter fish are found to be rather larger than those taken in summer, while among the fish commercially termed "maties" there are (1) immature herring, *i.e.* herring which, in addition to being small in size, have undeveloped milts or roes; (2) small herring in all degrees of ripeness up to maturity; (3) small herring which have spawned—small "spent" herring. Hitherto, the size of the fish, rather than the sexual condition, has apparently determined whether the term "matie" should be applied. In the same districts, and even in the same shoals, *large* sexually immature herrings are often found along with *small* ripe, or nearly ripe, herring; hence herring appear not only to vary in size in their fully adult condition, but also to vary in the size at which they reach sexual maturity. It is pointed out that these results, as well as the fact that the undivided ova vary in size in ratio to the size of the fish, are likely to cause considerable variation in the progeny which result from the interbreeding of fish of varying *size* and age. Of the fish caught in the early part of the season, a much larger proportion are immature and small, and probably also younger than is the case later on. The adult fish appear to reach a more advanced stage of ripeness before they approach the spawning-banks. From the measurements made, it is shown that the length of the head varies considerably the extremes being found in herrings of all localities and both seasons, the percentage with the larger size of head being rather greater among the winter than the summer herring; but this difference, like that of the total length, is considered insufficient to prove a racial distinction. The position of the centre of the dorsal fin in a majority of the winter herrings is anterior to the centre of the body, whereas among the summer herrings a large percentage have it behind the centre. In the immature fish, however, the fin-centre is generally anterior to the body-centre. The anal and pelvic fins show a corresponding difference in position. As regards the pelvic fin, however, this condition is limited to the adult and larger young herring, the pelvic fin being found, like that of the sprat, anterior to the dorsal fin in young herring below 60 millimetres in length. The pectoral fin varies very slightly in its relative position on the winter and summer herring. The relative basal length of both the dorsal and anal fins conveys no indication of racial distinction between the summer and winter fish. The dorsal fin is in all the herrings generally longer than the anal; only about $1\frac{1}{2}$ per cent. of the summer herrings, and $7\frac{1}{2}$ per cent. of the winter, having the anal fin longer than the dorsal. Further details are given respecting the number of fin-rays, keeled scales, circumstances of spawning, &c., but which scarcely affect the question of racial distinction. The inquiry, so far as it has gone, tends to prove that there is no racial distinction between the herrings found in the various localities around the Scottish coast. Judging, however, from the more backward position of the dorsal pelvic and anal fins, the doubtfully smaller head, and the slightly lesser size of the summer herrings, more minute inquiries may indicate a slight difference between the winter and summer herrings.

Mr. Brook reports on the herring-fishery of Loch Fyne and the adjacent districts during 1885, and under his "Ichthyological Notes" gives a short account of the rare fishes met with during the year.

Naturalists and fishermen alike have long felt the absence of accurate information as to the spawning period of fishes. In order to have a basis on which to found further investigations, Mr. Brook has prepared a provisional list of the spawning period of various food-fishes. This list brings out the great lack of accurate information on the subject, but gives an idea of the opinions as to the spawning periods held by fishermen and others around our coast. These opinions are in many cases conflicting, and in most cases they will require to be altered. Prof. McIntosh contributes an account of the work undertaken at St. Andrews since the last Report, including notes on the eggs and young of fishes studied during the past year. Recently considerable attention has been devoted by Mr. Wilson to the development of the common mussel, and an account of his investigations up to the present time will be found in the appendix. During the summer and early autumn several attempts were made to fertilise the eggs artificially at St. Andrews. The early stages of development were studied from ova obtained in this manner, while the free-swimming embryos were frequently obtained in pools amongst the mussel beds in the Eden and in other localities. In the Board's last Report it was mentioned that Prof. Greenfield had undertaken to investigate the lower organisms met with in some of our more important salmon-rivers. This investigation has been advanced a step, and numerous forms have been isolated and cultivated by the methods previously described.

Mr. Brook and Mr. Calderwood give the further results of examination of the food of these "useful" fishes, the herring, the cod, and the haddock. Mr. Calderwood also sends notes on the Copepods of Loch Fyne, and on the Greenland shark; Canon Norman reports on a Crangon, some Schizopoda, a member of the order Cumacea, new to, or rare in, the British seas; Dr. Stirling, on red and pale muscles in fishes, and on economic products from fish and corresponding vegetable products; Mr. Haliburton, on the blood of *Nephrops norwegicus*; Dr. John Gibson, on physical observations made for the Fishery Board in the Moray Firth during the autumn of 1883.

Ten plates accompany the appendix. It is greatly to be regretted that the Board has not yet been able to survey some of the fishing-banks, more especially those which are supposed to extend along the western shores of the Hebrides, and that the part of the Report dealing with scientific work is not published separately.

THE ELECTRIC CHARGE ON THE ATOM

ALTHOUGH considerable attention has been given of late to electrolysis and the subjects connected therewith by English chemists, more especially since the Helmholtz Faraday Lecture of 1881, yet some of Prof. Helmholtz's deductions from Faraday's experiments have been curiously neglected.

I refer more especially to the bearing of the facts on the true nature of valency, and I purpose in this paper to point out one or two fairly obvious consequences which follow from the results of Faraday's researches, but which have not, I believe, been stated before.

Prof. Helmholtz has shown that it follows from Faraday's experiments on electrolysis that while a monovalent atom carries to the electrode one charge of electricity a divalent atom carries two charges of electricity. For instance, when we electrolyse potassium chloride, we have each potassium atom delivering a charge of electricity at the one electrode, and each chlorine atom delivering an equal charge of electricity at the other electrode, all monovalent atoms, carrying with them an equal charge of electricity, which we may call the unit charge.

When, however, we electrolyse magnesium chloride, we have two atoms of chlorine set free for one of magnesium, and consequently while each chlorine atom carries its unit charge with it, the magnesium atom carries two units of electricity to the electrode. In fact electrolysis proves that differences of valency mean differences in the electrical charge on the atom. All this is so familiar to us now that I have perhaps repeated it at unnecessary length.

But we have many elements which vary in valency. For instance, copper is capable of forming two series of compounds, in one of which it is monovalent, and in the other divalent, that is, in one of which the copper atom carries one unit charge of electricity, and in the other carries two units of electricity.

We are able, then, under certain conditions to alter the electrical charge on an atom, increasing it by some simple multiple.

There are therefore a special group of chemical reactions, such as the oxidation of the cuprous salts, in which we have not merely combinations between two or more substances, or ordinary double decomposition, but in which, besides such changes, an additional electrical charge is given to, or removed from, an atom. I think it follows from this that all such reactions are of very special interest, and deserve careful study.

For instance, take the case of the saturation of an olefine by chlorine. We must look on this reaction from one of two points of view. Either on the addition of chlorine an additional charge is supplied to the carbon atom, in which case by-products of less saturation are probably formed; or the carbon atom is already fully charged, in which case the double bond is not merely a shorthand statement of a possible reaction, but expresses a physical fact.

There is also another point worthy of note in connection with this addition of electricity to the atom. If we take the case of the two copper chlorides—cuprous and cupric chloride—we find that their heat of formation per chlorine atom is not very different. Now it is well known that the heat of formation of a salt approximates to the heat of formation as calculated from the electromotive force developed when that salt is formed in a voltaic cell.

To put this in other words, we can obtain from the heat of formation of cuprous chloride, or of cupric chloride, an approximate calculation of the difference of electric potential between the copper atom and the chlorine atom in the two salts.

Now, as already stated, the heat of formation per chlorine atom is nearly the same; that is, the difference of potential between the copper and chlorine is nearly the same in both salts. What follows from this?

It follows that, in doubling the electric charge on the copper atom, the potential is not also doubled. This means, therefore, that the capacity for electricity of the atom is increased at the same time. This conclusion is not quite certain, as our information is still too scanty on the actual differences of potential in the case of these two salts; and, further, we do not know what fraction of it belongs to the chlorine atom; but, on the whole, the facts we have point to the above conclusion, and it is at any rate a subject well worthy of study to determine whether the capacity of the atom for electricity can vary or not.

Passing from this, I wish to point out another very obvious but nevertheless important deduction to be made from the facts of electrolysis.

We have recognised that the difference between monovalent and divalent copper consists in the doubling of the charge upon the atom. This again may be due to some profound change in the atom itself, but it is at any rate the obvious and marked distinction; we have copper in both cases, but double the electrical charge in one case over that in the other.

If we searched among the elements, could we find two series of salts more completely different in their nature and properties than the cuprous and cupric salts?

I venture to say that, if we did not know we could derive the same element from both, we should assume them to be derived from two different elements, and assign them very different places in Mendelejeff's table. Many other examples of the same thing will occur to everybody, namely, that alteration of the electrical charge on the atom is accompanied by profound alteration in the nature of its compounds, and is therefore probably the cause of this alteration.

Up to this point I think my deductions are fair and obvious deductions from the facts of electrolysis. I wish now to suggest a possibility, I can call it no more, which if true will considerably alter our views of the facts of chemistry. We have found the importance of alterations of electrical charge in altering the properties of an atom as shown in its compounds.

We already believe that variations in atomic weight are closely allied with the variations in the properties of the atom as shown in its compounds.

Are there, then, two things which condition the chemical properties of an atom, or is there only one?

Let us look again for an instant at the facts of electrolysis, and let us take the electrolysis of hydrochloric acid as our example.

At present we state the facts thus:—Every molecule of hydrochloric acid consists of one atom of chlorine and one atom of hydrogen, the chlorine atom weighing 35·5, the hydrogen atom weighing 1. On passing a current, each molecule is split into these two atoms, each atom carrying a unit charge of electricity.

Is it not just possible that we may some day state the facts thus:—A molecule of hydrochloric acid consists of one molecule of hydrogen weighing 1 combined with 35·5 molecules of chlorine each weighing 1. On electrolysis, the chlorine atoms are split from the hydrogen atom, the chlorine atoms each carrying unit charge of electricity, and the hydrogen atom carrying 35·5 charges of electricity.[1]

If this is the truth, then all the atoms of the elements are of the same weight, and probably are made of the same "stuff," and we have two, and only two, things which condition the properties of the atom—namely, its electrical charge and its electric potential, and Mendelejeff's table becomes a statement of the periodic relationship between these.

[1] No one need quibble about the 35·5.

In suggesting this vague possibility, I do not wish to obscure the first part of the paper, which consists, I believe, of perfectly legitimate deductions from the facts of electrolysis.

I have purposely avoided giving many examples, as I have been dealing with such familiar and common-place chemical reactions that plenty of examples will at once occur to every reader; and sufficient has, I think, been said to show at any rate the importance of experimental inquiry into this subject, and the probability of considerable modifications of our views of chemical facts in the near future.

The new way of looking on valency, which we owe to Prof. Helmholtz, may, as I have already pointed out, completely alter our conception of the nature of an unsaturated carbon compound, and of the process by which saturation takes place; and probably as investigation proceeds in this department it will become necessary to re-dissolve our chemical facts and crystallise them out in completely new mental concepts, while doubtless the ideas associated with the graphic formula pass away and leave not a wrack behind.

A. P. LAURIE

MUSIC AND MATHEMATICS

YESTERDAY afternoon meeting at a friend's house a lady visitor to Oxford who was to sing that evening at one of the hebdomadal concerts in Balliol College, and the conversation happening to turn on the gifted mathematical lady Professor in the University of Stockholm, my thoughts shaped themselves, as I was walking home, into the following lines, which, if likely to interest any of your readers, I shall be happy to see appear in the world-wide-diffused columns of NATURE.

New College, November 15 J. J. SYLVESTER

SONNET

To a Young Lady about to sing at a Sunday Evening Concert in Balliol College

Fair maid! whose voice calls Music from the skies
Weaving amidst pale glimpses of the moon
Tones with fresh hues of glowing fancy strewn
And soft as dew that falls from pitying eyes—
Let from their virgin fount those accents rise
That bid sad Philomel suspend her tune,
Thinking the lark doth chant his lay too soon—
Whose else that trill which with her own note vies!
To her whose star shines bright o'er Maelar lake
And thee who beautifi'st glad Isis' shore
Grant! I one joint harmonious garland bind:
Thou canst with sounds our senses captive take -
She the true Muse, fond poets feigned of yore,
Strike Heaven's own lyre, Nature's o'erruling mind.

NOTES

MR. HAROLD B. DIXON has been appointed Professor of Chemistry and Director of the Chemical Laboratories at Owens College, Manchester.

THE *Oxford Magazine* announces that Prof. Burdon Sanderson and Mr. Gotch are going to spend their Christmas vacation at Arcachon, where there is awaiting them a large tank full of torpedoes. It looks forward with interest to the publication of the results of the Oxford physiologists' holiday, remarking that "to the research will be added the pleasing excitement of danger; for if incautiously handled these torpedoes will give the physiologist a shock, compared with which the agonies of scores of vivisected rabbits are as nothing." Of course this is not true.

Mr. William Fawcett, one of the assistants in the Department of Botany in the British Museum, has been appointed by the Secretary of State for the Colonies to the post of Director of the Public Gardens and Plantations in Jamaica.

The Uralian Society of Natural Sciences is arranging to hold a Scientific and Industrial Exhibition of Siberia and the Ural Mountains in 1887, at Ekaterinburg. The Exhibition promises to be of great scientific interest, including sections of geology, botany, zoology, anthropology, and archæology. The anthropology especially will be of the most comprehensive character. It will include a certain number of families of Bashkirs, Kirghizes, Vogones, Ostiaks, Samoiedes, and other half-civilised peoples of Siberia, with their dwellings, and appliances for hunting and fishing, besides models, figures, costumes, &c. There will also be a large collection of prehistoric objects. The grounds around the Exhibition building will be utilised to give a fairly accurate idea of the arborescent vegetation of the countries represented. Delegates from foreign Societies intending to visit the Exhibition will be accorded special travelling privileges, and be received with the greatest hospitality. The Exhibition will be open from May 27 to September 27. The President of the Society is General Ivanoff, and the President of the Exhibition Committee M. A. Miclowsky.

Mr. Arthur Grote died on the 4th inst. at his residence in Ovington Square. He was born in 1814. He was a Fellow of the Royal Society and also of the Linnean Society. Mr. Grote wrote a number of papers on subjects connected with botany and natural history, and contributed an introduction to Hewitson's "Descriptions of New Indian Lepidopterous Insects in the Atkinson Collection." He was engaged for many years in Her Majesty's Indian Civil Service.

Mr. W. Galloway writes with reference to the recent explosion at Elemore Pit:—"Elemore Pit is one of the Heeltan group of collieries near Newcastle-on-Tyne, which are accounted to be amongst the best and most carefully managed mines in this or any other country. It is under the direct supervision of Mr. Lindsay Wood—a member of the late Royal Commission on Accidents in Mines. The workings are dry and dusty; no accumulation of gas was known to exist anywhere; a shot is supposed to have been fired at the moment the explosion took place, for shot-firing was going on. The explosion appears to have been confined to the in-take air-ways, and to have shot up the downcast shaft, or, in other words, to have traversed a region filled with fresh air without any admixture of fire-damp. These features of this and other similar explosions of late appear to militate somewhat against the views expressed in the Report of the Royal Commission on Accidents in Mines, to the effect that coal-dust alone was a comparatively harmless agent in the absence of fire-damp."

The following are the arrangements for the lectures before Easter at the Royal Institution:—Prof. Dewar, six lectures (adapted to a juvenile auditory) on "The Chemistry of Light and Photography"; Prof. Gamgee, eleven lectures on "The Function of Respiration"; Prof. Rücker, five lectures on "Molecular Forces"; Prof. Max Müller, three lectures on "The Science of Thought"; Mr. Carl Armbruster, five lectures on "Modern Composers of Classical Song"; and Lord Rayleigh, six lectures on "Sound." The following are the probable arrangements for the Friday evening meetings before Easter:—Sir William Thomson, on "The Probable Origin, the Total Amount, and the Possible Duration of the Sun's Heat"; Mr. W. Baldwin Spencer, on "The Pineal Eye in Lizards"; Mr. Edwin Freshfield, on "Some Unpublished Records of the City of London"; Mr. E. B. Poulton, on "Gilded Chrysalides"; Mr. W. Crookes, on "Genesis of Elements"; Capt. Abney, on "Sunlight Colours"; Mr. V. Horsley, on "Brain Surgery in the Stone Ages"; Archdeacon Farrar, on "Society in the Fourth Century A.D."; Mr. G. J. Romanes, on "Mental Differences between Men and Women"; and Lord Rayleigh, on "Colours of Thin Plates."

An Edinburgh Correspondent writes:—"Mr. Romanes has just delivered his first course of lectures on the Philosophy of Natural History to a large and appreciative audience, including students from all the Faculties in the University of Edinburgh."

The Minister of French Postal Telegraphy has sent to Brussels a delegate to arrange for establishing a telephonic line between Paris and that city. The price for the use of the telephone will be five francs for a period of five minutes. It is the first step on record towards an international telephonic system.

A remarkable fire-ball was seen at Stonyhurst College, Blackburn, on December 4, at 9.16 p.m. Although the moon was shining brightly, it lit up the sky like a brilliant rocket. Its course was from 27 Lyncis to θ Gemini, and as it advanced it left a fine streak behind it. Its colour was a bluish-white. At first it moved swiftly, then more slowly, and, before vanishing, burst into several fragments. There was no streak left where the meteor burst, but only in the first part of its course. It was like a horse-tail cirrhus, the bushy portion surrounding the star 27 Lyncis, and thence extending in a narrower streak about 3°. It remained visible for one minute and a half, the part last to fade being that about 27 Lyncis.

We have received the last number (part 2, vol. iv.) of the *Proceedings* of the Liverpool Geological Society. The presidential address by Mr. Mellard Reade, "On the North Atlantic as a Geological Magazine," is a continuation of the line of investigation sketched out by him in his previous address, which was entitled "Denudation of the two Americas." The papers deal mainly with the geology of Liverpool and the neighbourhood, especially North Wales. A paper by the Secretary, Mr. W. Hewitt, "On the Topography of Liverpool," must be specially interesting and instructive to those acquainted with the present geography of that great city.

The active volcano, Asamayama, appears to be attracting particular attention just now in Japan, probably because it is the loftiest mountain in the country which is in a constant state of activity, and also because it is the nearest to the capital, and is situated in a district long famous for its health resorts. A few weeks since we referred to an anonymous account of the crater, published in the *Japan Weekly Mail*, but a much more careful sketch of it is given by the Japan Correspondent of the *Times* in a letter published recently in that journal. The roar of the volcano, on approaching the edge of the crater, he describes as not unlike the noise produced by the passage of a train across a bridge under which one is standing. There was no shaking, however, but loud hissing and bubbling constantly proceeded from numberless vapour-jets in the inner face of the crater-wall, from its rim downwards. The crater is a rough oval in shape, but the estimates of its size are most conflicting. The Japanese give the circumference as four miles, but this is simply a wild guess. A German explorer set down the diameter at 1100 yards, and an English mathematical professor put it at only 200 yards, "divergences that will illustrate the mental confusion to which some men are liable when in the presence of dread natural phenomena." The writer himself estimated the circumference at 1056 yards, by walking round the windward half of it—it was impossible to pass through the vapours on the lee side—which was accomplished in six minutes, at the rate of about three miles an hour.

On the very interesting question of the depth of the crater—that is, the depth from the mouth to the surface of the molten matter—opinions vary almost as hopelessly as on the size. No doubt the "vast clouds of the most pungent sulphurous steam," which are described as rising swiftly out of the caldron, render exact observation difficult. The *Times* Correspondent speaks of catching glimpses of the crater-wall at depths which a very moderate estimate would place at 300 feet. But the gradual convergence of the cavity apparent at this depth forbids the acceptance of the enormous profundity for which some visitors have contended, and suggests that the depth can hardly much exceed 500 feet. After a weird description of the appearance presented to the spectator by the volcano at work, the writer concludes by remarking that the present crater is apparently the youngest and innermost of three. Further down on the south west side are to be seen, along with numerous fissures of unfathomable depth, remains which point to the existence of two former craters, concentric and of large dimensions, and separated from one another by a considerable interval. Possibly the existing cone was formed by the great eruption of 1783.

A TELEGRAM from New York of December 2, states that eight slight shocks of earthquake are reported from Summerville, one severe shock from Columbia, and two slight ones from Charleston. No damage was caused. Dr. Forel writes that earthquakes were felt in Switzerland on November 25 at 3h. at Pontresina and Bernina (Grisons), and again at 3h. 58m. (both Greenwich times) at Pontresina.

ACCORDING to the *Ceylon Observer*, Mr. C. Stevens, a naturalist, has returned to Colombo from a most successful and interesting sojourn amongst the Veddahs, whose district he has thoroughly explored, and with whom he was enabled to establish a closer intimacy than any European ever did before. He has been able to clear up a good many dubious points relating to the manners, customs, and religious beliefs of these veritable wild men of the woods. He has succeeded in obtaining several perfect skeletons, and a number of skulls.

THE *London and China Telegraph* states that a Folk-Lore Society has been established in the Philippines, at the prompting of a Society for the study of folk-lore in Spain. The archipelago certainly presents a wide field for investigation and inquiry in this respect, on account of the diversity of native races inhabiting it. The survivals in the shape of traditions, customs, and observances amongst the primitive tribes still to be found in the inaccessible interior of many of the islands may be expected to throw much light on the early history of the people, and on the origin of many superstitious practices common in more civilised lands.

THE Report of the Public Free Libraries of the City of Manchester, while expressing the deep regret of the Committee at the loss of Sir Thomas Baker, their chairman for nearly twenty-five years, is at the same time a testimonial to the ability and judgment with which the work under his care has been carried on. Additional libraries, a tenfold increase in circulation since the two first of them were opened, and over 4000 volumes withdrawn this year as *worn out*, are proofs of the earnestness of this work. Nor does the increase seem likely to cease, for the extension of the time of keeping open the reading-rooms till 10 o'clock, although it adds to the already long hours of those engaged in their management, is sure, we think, to increase their counter-attraction to the public-houses, and to bring up the number of visitors annually to the libraries to three millions. Two recently incorporated districts also have requested that equal advantages may be extended to them, and help in carrying this out has been liberally supplied by independent public bodies. A remarkably large proportion of books are taken out to be read in the reading-rooms. Boys especially avail themselves of these rooms on a Sunday, nearly twice as many of them attending then as on a week-day; a direct reversal of the practice of other classes. The success of Manchester is the more marked that so moderate a proportion of fiction is supplied to its readers.

THE additions to the Zoological Society's Gardens during the past week include two Macaque Monkeys (*Macacus cynomolgus* ♂ ♀) from India, presented by the Countess Dowager of Lonsdale; a Mona Monkey (*Cercopithecus mona* ♀) from West Africa, presented by Miss Bashall; a Domestic Sheep (*Ovis aries*, var.) from West Africa, presented by Sir Albert Kaye Rollitt, F.Z.S.; a Grey-striped Mouse (*Smithus vagus*) from the Tatra Mountain, presented by Dr. A. Wryesniowski; a Poë Honey-eater (*Prosthemadera novæ-zealandiæ*) from New Zealand, presented by Capt. B. J. Barlow, s.s. *Taimu*; a Blue-fronted Amazon (*Chrysotis æstiva*) from Brazil, presented by Miss Joachim; two Tuatera Lizards (*Sphenodon punctatus*) from New Zealand, presented by Dr. E. B. Parfitt; a Cerastes Viper (*Vipera cerastes*) from Egypt, presented by Mr. J. H. Leech, F.Z.S.; a Beisa Antelope (*Oryx beisa* ♂) from North-East Africa, a Rough Fox (*Canis rudis*) from Guiana, purchased; a Red Kangaroo (*Macropus rufus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

CORRECTIONS TO REFRACTION TABLES.—Prof. Cleveland Abbe, in a short note to the *Astronomische Nachrichten*, calls attention to the fact that the reading of the mercurial barometer which is used in the refraction-formula as an index to the density of the air is not a true index to the pressure controlling that density until it is corrected for the effect of the variations in gravity. The correction is accomplished by adding one more factor, g, for gravity, when the formula becomes—

$$R = \alpha \tan z \left(\frac{1 - 0{\cdot}00259 \cos 2\phi}{1 - 0{\cdot}00259 \cos 2\phi_0} \, BT \right)^A \gamma^\lambda,$$

where ϕ is the latitude of the observer, and ϕ_0 of the station for which the tables were computed. Prof. Cleveland Abbe considers that the omission of this correction for gravity may partly explain the origin of small systematic differences in the declinations of different star-catalogues, though such differences, so far as they are due to refraction, must also be caused by local irregularities in the distribution of pressure and temperature, which produce effects equivalent to slight inclinations of the horizontal planes of equal density. The systematic changes in his distribution, due to change of season, must introduce an annual variation in refraction similar to the effect of parallax, and it will occasion a difference in the refractions north and south of the zenith, which may often attain an appreciable amount.

COMET FINLAY (1886 *e*).—The following ephemeris by Dr Krueger, for Berlin midnight, is in continuation of that given in NATURE of November 25 (p. 85):—

1886	R.A. h. m. s.	Decl. ° ′	log r	log Δ	Brightness
Dec. 10	22 2 49	13 25·6 S.	0·0074	9·8941	3·1

The brightness at date of discovery is taken as unity.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 DECEMBER 12-18

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on December 12

Sun rises, 7h. 59m.; souths, 11h. 53m. 58·0s.; sets, 15h. 49m.; decl. on meridian, 23° 6′ S.: Sidereal Time at Sunset, 21h. 14m.

Moon (one day past Full) rises, 16h. 34m.*; souths, 0h. 29m.; sets, 8h. 27m.; decl. on meridian, 18° 57′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	6 15	10 43	15 11	18 3 S.
Venus	8 12	12 4	15 56	23 30 S.
Mars	10 10	14 6	18 2	23 1 S.
Jupiter	3 14	8 26	13 38	10 7 S.
Saturn	18 6*	2 9	10 12	21 33 N.

* Indicates that the rising is that of the preceding evening.

Occultations of Stars by the Moon (visible at Greenwich)

Dec.	Star	Mag.	Disap. h. m.	Reap. h. m.	Corresponding angles from vertex to right for inverted image ° °

			,,	17,	19 20	*M*

M signifies maximum; *m* minimum; m_2 secondary minimum.

Meteor-Showers

Moonlight interferes with meteor observation during the early part of the week, which is also less fruitful of meteors than are the first few days of the month. Amongst the radiants which have supplied meteors at this season are one in the constellation of the Lynx, R.A. 108°, Decl. 63° N., and one in Quadrans, R.A. 221°, Decl. + 53° N.

THE LAW OF STORMS IN THE EASTERN SEAS[1]

I. IN the Eastern seas the earliest signs of a typhoon are clouds of the cirrus type—looking like fine hair, feathers or small pale white tufts of wool—travelling from the east or thereabout, their direction backing towards the north, a slight rise in the barometer, clear and dry but hot weather, and light winds. This fine weather lasts for days, and the existence of a typhoon at a great distance contributes therefore to the safety of ships at sea,—a fact that is not sufficiently appreciated by mariners.

The cirrus clouds, which frequently assume fantastic shapes, make their appearance within 1500 miles of the centre of a typhoon, the barometer is generally rising beyond from 600 to 1000 miles of the centre, and the mean of the twenty-four hours' temperature rises in Hong Kong above 81°.

A swell in the sea is noticed within from 300 to 500 miles of the centre, but this depends greatly upon the situation of the nearest land. Halos round the sun and the moon, phosphorescence of the water, and also glorious sunsets appear to be frequently noticed before typhoons.

Within about 800 miles of the centre the sky is generally half covered with cumulus clouds, above which cirro-cumulus are usually seen. South and south-west of the centre, thunderstorms and cumulo-stratus clouds are observed. On approaching nearer to the centre the cloudiness increases, the temperature falls in consequence, and the mercury begins to descend in the barometer. Then the air becomes oppressive from the increasing dampness, a slight haze is observed during the morning hours, and the sky presents a threatening and vaporous appearance. Within 300 miles of the centre the temperature falls quickly owing to the cumulus, roll-cumulus, or nimbus clouds, with which the sky is nearly completely overcast. And meantime the wind has risen and blows generally with the force of a strong breeze about 300 miles from the centre. But this depends also upon the bearing of the centre, the wind being usually strongest in the right hand semicircle. Within 150 miles of the centre the sky is densely overcast with nimbus clouds accompanied by heavy rain, and within 60 miles it generally pours down in torrents, while the wind blows so hard that no canvas can withstand it; but there is no thunder and lightning. The temperature at sea is frequently about 76°, and on shore about 78°.

Within from 2 to 15 miles of the centre the wind either calms down or blow only moderate breezes, and the sky clears, being now covered only by very light clouds. The sea is as a rule mountainous, but in some reports it is stated that the sea had calmed down to some extent when the wind fell. Quantities of sea-birds, and near land also butterflies and other insects, cover a ship situated in the bull's eye of a typhoon. It is possible that the central calm does not quite accurately coincide with the centre of the typhoon.

The angle between the direction of the wind and the direction of the radius (the straight line between the observer and the centre of the typhoon) is, on an average, between 10° and 25° latitude, 43° in front of the centre and 53° behind the centre; between 33° and 35° latitude, 65° in front and 85° behind; and between 10° and 35° it is about 49° in front and 62° behind the centre. The angle appears to be smaller near the shore for off-shore winds, and far out at sea the difference between the angle in front of and behind the centre appears to be small. The following rule for finding, on board ship in the China seas, the bearing of the centre of a typhoon is, therefore, approximately correct: Stand with your back to the wind, and you will have the centre on your left side, but 3 points in front of your left hand; *i.e. the centre bears about* 11 *points from the wind.* If your ship is in a very low latitude the centre may lie as much as 4 points in front of your left hand, *i.e.* bear 12 points from the wind, and if you are in a high latitude it may bear only 9 points from the wind. Once the wind has reached the force of a strong breeze, the average angle between the wind and the direction of the centre does not appear to change at all, but the wind, which blows in great gusts in a typhoon, may oscillate to both sides of the true value. There does not appear to be any foundation at all for the belief that the wind near the centre blows in circles round the centre. To act according to this rule might prove disastrous to a ship experiencing a typhoon.

Very low clouds in a typhoon move with the wind, but if the clouds are high they are frequently seen to move in a different manner, and the following rule may then occasionally be of use: If right in front of the centre, stand with your back towards the direction whence the clouds are coming, and you will have the centre from 1 to 2 points in front of your left hand; and if straight behind the centre you may have it a point or two to the left of the direction in which you are looking.

Once the bearing of the centre has been ascertained, the master of a vessel in a typhoon requires to know in which semicircle, looking in the direction towards which the typhoon is moving, he is situated: If *in the right hand semicircle, the wind will veer, i.e.* shift with the sun; and if *in the left hand semicircle, it will back, i.e.* shift in the opposite direction. But this rule is strictly applicable on board of a vessel only when hove-to, or at any rate proceeding at a slower rate than the typhoon. For a vessel moving at a faster rate than and in the same direction as a typhoon, the rule may be reversed. In case of doubt it may therefore become advisable to heave-to in order to be quite sure of the semicircle in which you are situated. But we have seen that the wind moves in spirals towards the centre, and

[1] By Dr. W. Doberck, Hong Kong Government Astronomer. Reprinted from the *Hong Kong Telegraph*.

it is therefore dangerous to lie-to in a typhoon, particularly before you are sure that the centre is past. Vessels near the coast of China, or in the Formosa Channel, generally seek refuge in the nearest typhoon harbour indicated in the Directory.

The wind shifts faster the nearer the centre you are. If the barometer falls rapidly and the wind does not change its direction, and when the gusts continue to increase in force, your ship is in danger of entering into the central calm of the depression with its mountainous and confused seas, which is by all means to be avoided, as it is the high cross seas that do the most damage, and not the force of the wind. When once you are caught in a typhoon you should make no sail, except what may be necessary to steady the ship, till the gusts continue to decrease in force and the barometer has risen for some time. Very deceitful lulls are reported to occur during the raging of a typhoon. The master of a sailing-vessel is said to have put up topgallant sails after getting into the central calm. Of course he could have had no reliable barometer on board.

In storms encountered in higher latitudes, where the incurvature of the wind is not so great as in a tropical hurricane, the right-hand semicircle is termed the dangerous semicircle, as a ship running before the wind is in more danger of crossing the path of the storm in front of the centre and perhaps be overtaken by it; but in a typhoon there is not much to choose between the semicircles. A dismasted ship is in danger of being carried into the centre from any quarter.

However, the right-hand semicircle is also in a typhoon generally more dangerous than the other, both with regard to the risk of crossing the path in front of the centre, and also, as remarked above, with regard to the force of the wind and consequent greater sea disturbance. A ship experiencing a northerly gale and a falling barometer in the China Sea in the typhoon season is generally in greater danger than another experiencing a south-westerly gale.

When you have ascertained in which semicircle your vessel is situated, you should, if in the right-hand semicircle, keep the wind as long as possible on the starboard tack; and if in the left-hand semicircle, you should run on the starboard tack, or heave-to on the port tack, so as to let the ship come up as the wind backs and run no risk of being taken aback. As explained further on, a typhoon encountered in a low latitude moves so slowly that a steamer or fast sailing-ship has a fair chance of running away from it, but farther north, when the centre proceeds at the rate of thirty or forty miles an hour, it requires careful management even supposing you have ample sea-room.

Typhoons are dangerous on the open sea, but they are still more to be feared in open anchorages or near lee shores. Along the south-west coast of Formosa and elsewhere, a ship must in the south-west monsoon be prepared to run to sea at very short notice, as in some of the harbours you could not lie with any chance of riding out a typhoon. A steamer at anchor should get up steam as soon as the wind rises above the force of a strong breeze, and a sailing-vessel should take down the top-masts. The direction in which the wind is going to shift must early be determined so as to select a sheltered anchorage. If the centre passes very near the anchorage, the berth may have to be changed to the other shore during the lull, before the wind shifts to the opposite quarter.

A ship moored by a single anchor with her head to the wind, will swing with the sun in the right-hand semicircle and against the sun in the left-hand semicircle. If two anchors are dropped, the anchor on the advancing bow should be let go first, therefore a ship in the right-hand semicircle of a typhoon should first drop the port anchor and afterwards the starboard, in order that she may ride with open hawse. And a ship in the left-hand semicircle should first drop the starboard anchor. But ships have to ride with a long scope in a typhoon, and as they are liable to drag the anchors, some prefer to drop the second anchor to veer upon if the first should not hold.

II. The force of the wind and the appearance of the sky do not always furnish a reliable guide to determine how far you are from the centre of a typhoon. The dimensions are different in different typhoons, and near land the strong winds are often so irregularly distributed that in a place near the centre less wind may actually be experienced than at some distance farther away from it. Also the 11-point rule for ascertaining the bearing of the centre fails near some shores if the centre is not near at hand; thus there often blows a steady easterly gale along the southern coast of China when a typhoon is crossing the China Sea, and the gale blows often steady from north-east about the northern entrance to the Formosa Channel when there is a typhoon in a more southern latitude.

The surest of all warnings is furnished by the standard barometer on shore and the compensated aneroid on board ship; you are all right if you can put your vessel on the tack that will keep your barometer rising. But in order to understand the indications of the barometer you will have to keep a regular meteorological register. The master of a vessel who does not look at his aneroid till he is in a typhoon, does not derive half the benefits from his observations that he would have enjoyed had he watched it beforehand. He might perhaps have avoided the weather he is now experiencing, or even have benefited by the favourable winds and sailed round the typhoon. No doubt the time is approaching when underwriters will stipulate that the indications of an aneroid or a marine barometer must be regularly registered on board a vessel insured by them.

On the other hand, it would not be fair to ask the mariners to keep complete meteorological records, such as are kept in the lighthouses out here. Some seamen have a taste for this kind of work and make very useful and fairly accurate observations, but, for instance, the readings of dry and damp bulb thermometers taken on many vessels are of very little use.

The tube of the marine barometer has to be so much contracted to stand the incessant pumping and danger of breakage, that the instrument is sluggish and often reads half an inch or more too high near the centre of a typhoon. Some cheap wooden barometers cannot be registered below a certain height, the cistern being too small to hold the mercury that comes out of the tube. Of course some cheap aneroids are no better, and even a first-class compensated instrument requires to be thoroughly verified, as the scale is never quite correct, but they act nearly as quickly as first-class standard barometers, and for use on board ship the instrument that is quickest in its indications must be preferred. The objection to the use of the aneroid is founded on the fact that its index-correction changes gradually; but then this can be determined and allowed for by reading it off as often as the vessel enters a port, such as Hong Kong, where correct meteorological observations are constantly being made.

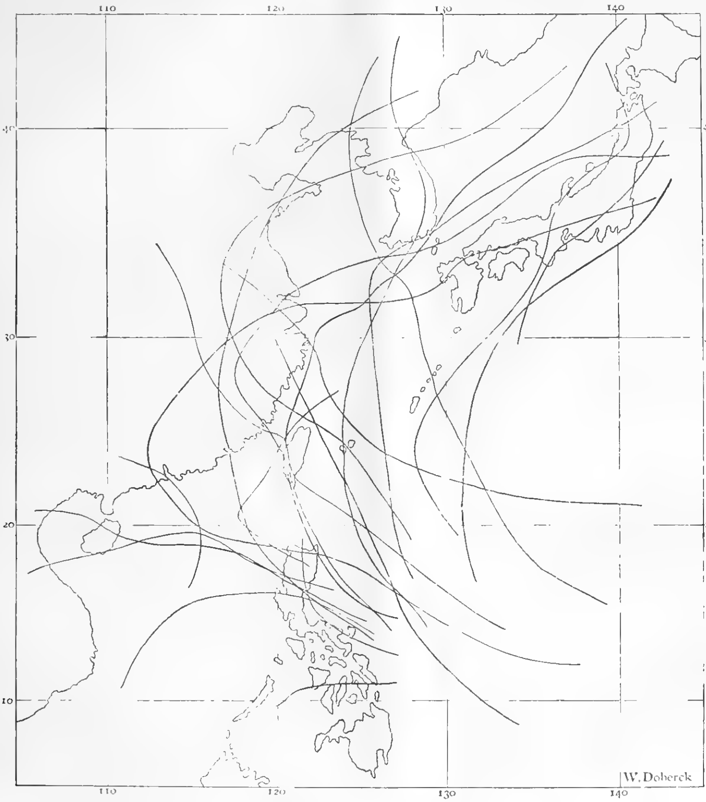
The best hours for making observations are 4 a.m., 8 a.m., &c., up to midnight inclusive. The observations should consist in readings of the aneroid, temperature (this is no use except when the thermometer is placed well forward so as to be exposed to the wind, though in a position sheltered from the sun and the rain), direction and force (0–12) of the wind, direction whence coming of the clouds, amount (0–9) of sea-disturbance, and weather (Beaufort's notation). For further particulars the "Instructions for making Meteorological Observations, prepared for use in China," published in 1883 by the writer, may be consulted.

From 4 a.m. to 10 a.m. the barometer is rising, falling from 10 a.m. to 4 p.m., rising from 4 p.m. to 10 p.m., and falling from 10 p.m. to 4 a.m. It reads highest at 10 a.m. and lowest at 4 p.m. During the approach of a typhoon this regular daily variation may be masked, but it goes on all the same, and must be taken into account when the barometer begins to fall before a typhoon. Thus if it has fallen a certain amount between 10 a.m. and 4 p.m. you must subtract the normal descent between these hours in order to know how much of the fall is due to the approach of the typhoon, and if it were between 4 p.m. and 10 p.m. that it fell, you must add the normal rise for the same purpose.

In many typhoons, the barometer, reduced to 32° Fahrenheit, and to sea-level, does not fall below 28·80 inches. In others it falls as low as 28·50. Lower readings of the barometer appear to be rare, but it has been stated to have fallen much lower. The rate at which your barometer is falling depends upon your approach to the centre, and in consequence upon the rate at which this is travelling. For this reason it is not safe to draw conclusions concerning the amount of wind to be expected from the rate at which the barometer is falling, but to some extent, of course, this may be done. Remember, that, when the barometer has fallen to its lowest reading and begins to rise, you may expect to experience as much bad weather as you have already gone through.

The wind blows from a region where the barometric pressure is higher, towards one where it is lower, being, however, deflected towards the right in a typhoon, and the force of the wind depends upon the difference of pressure between one place and another situated in the direction of the greatest barometric slope or gradient. This is expressed in hundredths of an inch per fifteen nautical miles. Now, the gradient corresponding to a certain force of the wind is somewhat uncertain, particularly when the force of the wind exceeds a whole gale, but on an average a gradient of 0·02 inches in 15 miles corresponds to a force of wind equal to 6 on Beaufort's scale, 0·03 to 7, 0·04 to 8, 0·05 to 9, 0·07 to 10, 0·10 to 11, and where the gradient is above a tenth of an inch in fifteen miles it generally blows with full typhoon force. In low latitudes the gradient occasionally exceeds one inch in fifteen miles.

Curved lines drawn on a map through the places from which the same height of the barometer (reduced) is reported, or between those that report a higher and a lower barometer, are called isobars. The gradient lies at a right angle to the isobar. These are the most important elements in forecasting the weather. Thus during the south-west monsoon the barometer as a rule reads higher over Luzon than along the China coast, the gradient being directed from about south-east towards north-west, indicating southerly winds as prevailing over the China Sea according to the 12-point rule. But when, as occasionally happens in the typhoon season during the south-west monsoon, readings reported from stations along the south-eastern coast of China are higher than those reported from Luzon, the gradient is found to be



Principal Typhoons of 1884 and 1885.

reversed, being directed towards south-east, thus indicating northerly winds. At such times a typhoon may be expected, and the probability is increased if the barometer is falling in Luzon and rising slowly in Northern China and Japan, and if cirrus clouds have previously been observed to come up from east or north.

III. Nearly all the typhoons appear to have their origin east or south-east of the Philippine Archipelago, in a part of the ocean south of the high-pressure area that covers the Northern Pacific in the summer season, which part of the ocean is characterised by high sea-surface temperature. Typhoons are sometimes formed in the China Sea, but then they seldom develop much energy, as they usually move quickly northwards and enter the mainland of China or Formosa. Owing to their small dimensions they are easily avoided by such ships as may fall in with them. The sea-disturbance is nothing terrible, and only whole gales of wind were reported in those cases that have been investigated here. If, however, a typhoon of this kind passes northwards up through the Formosa Channel, it soon becomes as formidable as any of those that originate in the tropical Pacific. We have not traced typhoons nearer to the equater than about 9°. But it appears that they may possibly in some cases originate nearer than that to the equator, as hurricanes have been encountered in a lower latitude.

It frequently happens that a vessel encountering a typhoon in, say, 12° north latitude and 135° longitude east of Greenwich, does not experience any strong wind or bad weather till within a hundred miles or so of the centre, and as the typhoons are most violent in that locality, it is very important to look out for the premonitory signs referred to in the first section of this article, taking into account that the dimensions of a typhoon are so small there. On the other hand, they move at so slow a rate that you may run away from them if you are aware of the danger in time, so much more as you may be sure that a typhoon in that locality is directing its course to somewhere about west-north-west or north-west, and most likely in the first-named direction. So it is better to get to the eastward of it. Nearer the Philippine Archipelago the typhoons usually take a more northerly course, moving north-west or north-north-westward. But frequently they continue their course west-north-westward and cross the islands to enter the China Sea. In spring and autumn they have even been found to move westward and turn south-westward after entering the China Sea. But when you are east of the Philippines you should try to get your ship south-east of the typhoon by crossing the path behind the centre, if possible. If you are going northwards, you will then benefit by the fresh south or south-west breezes, taking care not to approach too near to the typhoon, whose progressive motion may not be more than six miles an hour. You will probably have squally and wet weather.

When all the paths of the typhoons that have been investigated by the writer in the course of the last three years are laid down on a map of the Far East, the picture looks much like a fan, the paths, with a few stray exceptions, radiating from the locality referred to above, and running in all directions between west and north, but most of them at first westward and then north-westward. In a higher latitude they generally recurve and pass off to the north-east, after first, of course, having turned northwards. Every typhoon does not recurve; in fact, as stated above, some of them finally disappear in the China Sea after turning to the south-west. The others recurve between 20° and 40° latitude, and 115° and 130° longitude. The Middle Dog Lighthouse is situated in the centre of the region of recurvature.

The normal path is therefore, roughly speaking, a parabola, whose axis lies from east to west, and whose apex is turned westward and lies within the region indicated above. But each path individually is anything but a regular parabola, and the deviations are evidently due to the influence of the coast-line of the mainland of Asia and to the mountainous islands (especially the high mountains of Formosa) as well as to the prevailing winds. For there is no doubt that the progression of a typhoon is the effect of the wind prevailing at the time, not necessarily at the surface of the earth, but at a somewhat higher level in the atmosphere, which agrees with the direction of the clouds, that have, as explained in the first section of this article, been found to move nearly straight towards the centre in the posterior semicircle. If, however, the wind at the surface of the earth is strong, it is at times plainly seen to blow the typhoon before it. The typhoons do not appear to move south-westward in the China Sea except when the north-east monsoon is strong, and in the summer of 1885, when the south-west monsoon was strong, most of the typhoons moved northwards while yet to the east of Formosa. This is then the reason why the typhoons depend upon the season of the year. They are likewise deflected from their previous path when exposed to strong winds blowing out of open channels, such as the Formosa or Corea Channels, in which case the speed of their progress is sometimes abruptly increased.

The average rate of progress of the centre of a typhoon in 11° latitude is 5 miles an hour. In 13° it is 6½, in 15° it is 8, in 20° it is 9, in 25° it is 11, in 30° it is 14, and in 32½° latitude it is 17 miles an hour. The rate of progress does not vary perceptibly in case of typhoons south of 13° latitude, so it is well for masters of vessels to know this, but it is more variable the farther north you go. In 32½° latitude it ranges between 6 and 36 miles an hour, so that you cannot at all be sure that a typhoon, which you may happen to be near, will travel at anything like the average rate of progress in that latitude.

In "Observations and Researches made at the Hong Kong Observatory in the year 1884," the writer suggested the division of typhoons into four classes according to the paths which they usually follow. Of course abnormal instances, such as for instance are presented by the typhoons that originate in the China Sea, occur occasionally in China as well as elsewhere, but they are comparatively rare.

Typhoons of the first class occur at the beginning and the end of the typhoon season. They cross the China Sea and travel either in a west-north-westerly direction from the neighbourhood of Luzon towards Tonquin, passing south of or crossing the Island of Hainan, or, if pressure is high over Annam, they travel first westward and subsequently south-westward. They can generally be followed for between five and six days.

Typhoons of the second class are the most frequently encountered, and their paths can be traced farthest. They generally travel north-westward while in the neighbourhood of Luzon, and either strike the coast of China south of the Formosa Channel, in which case they as a rule abruptly lose the character of a tropical hurricane, recurve in the interior of China, re-enter the sea somewhere between Shanghai and Chefoo (thereby regaining some of their past violence), pass across or near to Corea, and are finally lost sight of in their motion towards about east-north-east; or they pass up through the Formosa Channel, recurve towards north-east, and pass along the coasts of Japan; or they may strike the coast of China north of Formosa. Typhoons following the latter path originate further east of the Philippines than the others. They either continue their motion north-westward, in which case they are soon lost, or recurve and pass north-eastward near Corea. Typhoons of the second class occur from June to September inclusive, but are most common in August and September. It appears that a third of the typhoons belong to this class. They can be followed on an average 7 days, or rather between 5 and 12 days.

Typhoons of the third class are probably the most numerous of all, but are not encountered so frequently as the typhoons of the second class, and therefore the existence of a typhoon of this class is sometimes only suspected, although it of course influences the weather along the eastern coast of China through the fine weather area with which it is surrounded. They pass to the east of Formosa, travelling northwards. After recurving, they generally pass near Japan, but sometimes a typhoon of this class continues to move north-north-westward and does not recurve till west of Corea. They prevail in the same season as typhoons of the second class, and may be traced on an average during 7 days, or more correctly between 3 and 12 days. A typhoon of this class frequently follows after one of the second class. It is a well-known fact that depressions are attracted towards places which have just been traversed by a depression.

Typhoons of the fourth class pass south of Luzon, travelling westward, or first in this direction and then south-westward. They occur at the beginning and the end of the typhoon season, while the north-east monsoon is strong, namely in April and late in autumn, but are very rare. They are said to be more violent in autumn than in spring. Existing in so low a latitude, their dimensions are, of course, very limited. The writer has not been able to follow them for more than a day or two.

The number of typhoons that are known to have occurred in each month of the year, expressed in percentages of the total number of typhoons, is as follows:—January 2, February 0, March 2, April 2, May 5, June 5, July 10, August 19, September 27, October 16, November 8, and December 3. These figures prove that typhoons are most frequent during the month of September, but they also show that, strictly speaking, there scarcely exists a well-marked typhoon season. On an average there are 15 typhoons every year, but typhoons in different years exhibit some variations.

IV. The writer on his arrival in the colony in 1883 found that meteorological observations were received from a few of the Treaty ports, &c., and were published in the local papers; and seeing that these returns would only have to be corrected and reduced, as well as slightly extended, in order to be of great value to the shipping, he took upon himself to effect this. Subsequently, as the official work of the Observatory was fully started, he would have had to give up this purpose had not the Government decided to support it. Thus originated the *China Coast Meteorological Register*, which is published daily from here. It contains, at present, observations of the principal meteorological elements, which are received through the co-operation of the great telegraph companies from Manilla, Bolinao (Luzon), Haiphong, Hong Kong, Amoy, Foochow, Shanghai, Nagasaki, and Vladivostock, but the number of the stations might with advantage be extended. It gives also information about the weather prevailing in the Far East, and more or less rough intimations concerning such typhoons as happen to be indicated by the telegraphic returns, as well as by local observations. Subsequently more or less extensive monthly meteorological returns are received from about fifty land stations in the Far East, and the examination of the log-books of ships calling at this port, as well as observations received from commanders of men-of-war and masters of vessels trading in these seas, furnish a perhaps unequalled amount of material for scientific discussion, the results of which, as far as they go, are from time to time published in the *Government Gazette.* But no funds are available for this work, the Observatory being supposed to make and investigate only local observations, and with reference to weather-intelligence to warn the colony of storms by which it may be threatened, as far as may be possible through local observations. Some distinguished individuals having the welfare of the colony at heart would gladly see the little Observatory extended into a Meteorological Office for the Far East, for which it would be so peculiarly adapted owing to its central position, extensive telegraphic connections, &c.; but where the money is to come from has not yet been suggested. The Meteorological Office in London is allowed over ninety thousand dollars a year. The area in question is considerably larger than the area covered by the United Kingdom. The annual cost of the local Observatory was estimated to begin at ten thousand dollars, and it was remarked that additional clerical help would certainly be needed if it were resolved to undertake a thorough investigation of the monsoons of the China Sea. But actually only about six thousand dollars a year are expended in connection with the Hong Kong Observatory.

The Colony itself is warned by means of the *typhoon gun*, placed at the foot of the mast for hoisting signals beside the time-ball tower. It is fired one round whenever a strong gale of wind is expected here, and two rounds whenever the wind is expected to blow with typhoon force. It will be fired again, if possible, when the wind is likely to suddenly shift round. In 1885 it was fired also as a mail gun, but this practice has been discontinued, and as long as the typhoon gun is not fired in future, one may be sure that no typhoon is expected here. During the approach of a typhoon, and at other times when it appears desirable, special messages are telegraphed from the Observatory to be distributed in Hong Kong in such manner as the Government may from time to time see fit to direct, but as soon as they are issued from here the writer's responsibility in the matter ceases. This arrangement will, however, be found to be of very little use until the Observatory is placed in direct communication with the telegraph offices in Hong Kong, as the connections between the police stations generally break down in bad weather, when there is no boat-communication with the other side of the harbour, and thus the colony may expect that communication with the Observatory will sometimes be interrupted just at such times when the intelligence issued from here would be particularly useful. As soon as direct communication with the telegraph offices is established, the daily returns from the Treaty ports will be telegraphed across the harbour, and the *China Coast Meteorological Register* can then be issued at an early hour, by which its utility will be very much increased.

In the course of the summer of 1884 the writer invented and started a system of *meteorological signals*, which continue to be hoisted on the mast beside the time-ball tower at Tsim-sha-tsui. As these signals could not be hoisted without friendly co-operation with the officials of foreign Governments, they are, of course, unofficial, using this word in the sense in which it is understood by scientific men. The utility of these signals is confined to the shipping and to those interested in ships about to leave the harbour, or out in the China Sea. *The colony itself is warned by means of the typhoon gun.*

A red drum is hoisted to indicated the existence of a typhoon felt in the China Sea in a longitude more easterly than the colony. Steamers, if bound for northern, western, or southern ports, should lose no time in starting, and may then expect more or less fine weather. Those bound for the Philippines should take precautions to avoid the typhoon, and observe the rules set forth in the first section of this article. Sailing-vessels bound for western or southern ports should lose no time in starting, but those that are bound for northern or eastern ports ought to remain in the harbour awaiting further information, as they may expect to fall in with calms or contrary breezes after starting, even should the wind be westerly here at the time. The day after the drum has been hoisted the *China Coast Meteorological Register* should be consulted, taking into account that typhoons east and south-east of Hong Kong generally travel at the rate of from six to fourteen miles an hour.

A red cone pointing upwards indicates that a typhoon exists in a latitude more northern than the colony, or that it is progressing towards the north. More or less persistent south-west winds, at times accompanied by thunderstorms, may then be expected, and ships leaving the harbour are not at all likely to run any risk from the typhoon. Sailing-vessels bound for the north should start as soon as convenient, so as to benefit by the favourable breeze to run through the Formosa Channel and avoid the way round Formosa. By following the latter route a sailing-vessel, moreover, runs the risk of encountering the next typhoon east of Formosa, particularly during the months of August and September.

A red cone pointing downwards indicates that a typhoon exists in a latitude more southern than the colony, or that it is progressing towards the south. As such a typhoon is likely to travel in a northerly direction, ships desirous of avoiding bad weather should await further instructions, or remain in port till the barometer begins to rise. Then the danger is past.

A red ball indicates that the typhoon exists in a longitude more westerly than the colony. Ships starting for northern, eastern, or southern ports may expect breezes from east round by south to south-west. Those starting for western ports run no risk as long as the barometer is rising. If it should happen to fall, they may heave-to, and subsequently, if necessary, take refuge in some typhoon anchorage, such as St. John's harbour, but this will rarely occur. If a vessel in the Formosa Channel experiences an increasing south-westerly gale and a falling barometer, the typhoon has very likely recurved. All you have to do in that case is to lie-to, when the weather will quickly improve, and you may expect a pleasant voyage.

V. As the typhoons during their entire course are nearly always moving northwards, or rather into a higher latitude, a ship situated in the southern semicircle is on the whole in a safer position than north of the centre. East of Luzon typhoons move west-north-westward, or thereabout, and a ship must shape its course so as to reach the quadrant south-east of the centre. As a general rule, they move north-westward in that part of the China Sea between Hong Kong, Luzon, and Formosa, and east of the latter island they generally travel in some direction between north-west and north. So your vessel is safest when south of the centre, where you must heave-to till the weather improves, particularly if bound for one of the northern ports. If bound for the south, you may run across the path in front of the centre with the north-westerly breeze, but if you are not in time you may lose your boats and sustain other damage.

About 30° latitude, between China and Japan, you are liable to fall in with a typhoon travelling in any direction between west-north-west, north, and east-north-east. Here you are as a rule safest when south of the centre, but if the typhoon is travelling north-eastward this is in the dangerous semicircle. However, the investigations of the writer, though he has paid less attention to typhoons near Japan than elsewhere, nevertheless indicate with some degree of probability that the wind is less incurving behind the centre in that locality than elsewhere. North of this latitude you would of course prefer to be west of the centre.

Suppose that after leaving Singapore bound for Hong Kong the south-west monsoon begins to blow fresher and the barometer to fall, and you suspect that a typhoon is raging in a latitude more northern than where you are at present (the phenomena mentioned would not necessarily indicate the existence of a typhoon, if they were not accompanied with some of the other signs enumerated in the first section of this article), you will, of course, set your course to the east in order to sail round the typhoon and benefit by the south-easterly backing to east winds which you may expect to fall in with; but if the season is late in the year, you had better assure yourself that the typhoon is not travelling south-westward, in which case you might possibly be overtaken by the centre. These typhoons are often the cause of high seas even in the Gulf of Siam; but as their progressive motion is usually rather slow, you may heave-to in order to make observations without losing ground perceptibly. Supposing a typhoon in the China Sea does not make itself felt till you have reached a higher latitude, and that it is passing westward in a latitude south of your ship; being in the dangerous semicircle, where the wind is, moreover, stronger than south of the centre, you may have to cross the path in front of the centre to arrive in the anterior left-hand quadrant; or, if the typhoon is yet distant, the wind light, and your ship thoroughly sea-worthy and in good trim, you may possibly put her on the port tack and run north-eastward, but be ready to change the tack as soon as it becomes advisable.

Many of the anchorages along the south-eastern coast of China and the south-western coast of Formosa afford excellent shelter against north-east winds, but would prove to be much worse than the open sea during a heavy southerly gale. If you observe a northerly gale and a falling barometer, by far the surest signs of an approaching typhoon, and appearances are rapidly getting worse, then occasions may possibly occur when you may be under the dire necessity of running southwards with the northerly gale, against the rules laid down by meteorologists, and bring your ship into a most dangerous position in front of the centre. But you may happen to be better off there after gaining ample sea-room, than in the snug anchorage, where your vessel would be smashed against the rocks as soon as she began to drag her anchors when the storm burst upon her from the south, although the south-west storms experienced along the south eastern coast of China during a typhoon that enters the mainland are as a rule less violent or protracted than the preceding storm from the north.

Suppose that after leaving Hong Kong bound for a northern port you were to ascertain the existence of a typhoon about to cross your course in front of your vessel, and you experience, say, a strong breeze from the west-north-west. If you do not alter your course, you may, from the fact of its subsequently appearing to be a hanging gale and seeing the mercury falling in the barometer, draw the erroneous conclusion that you are on the path of the centre of a typhoon coming down on you from the east-north-east. In such a case it does not appear to be advisable to scud before the wind, it being decidedly wiser to heave-to. Then if the gale is observed to begin to back towards south-west, you may run southwards and shape your course so as to sail round the typhoon. Masters of steamers leaving Hong Kong while the red drum is hoisted generally lose no time in running southwards as soon as the typhoon is observed to have taken a north-western course, and suffer very little delay in consequence.

Steamers bound for Shanghai are, while between Foochow and Ningpo, liable to experience the northerly gales that precede a typhoon of the second class travelling north-westward and about to strike the coast in that locality. Not wishing to expose their ships to the high cross seas round northern Formosa, the masters generally take them into the nearest typhoon harbour in order to wait till the centre has entered the mainland, and then run northwards with the southerly gale.

These few examples will be sufficient, the more so as the further consideration of the subject would lead into details with which the writer is not familiar, being possessed of no further knowledge of navigation than the little that can be gleaned from the inspection of log-books and from occasional conversations with masters of vessels of many years' standing. The writer has invariably found these gentlemen ready to recount their experiences and to communicate any information, as soon as they found that it was required for scientific purposes exclusively. The master of a vessel, after encountering a severe typhoon, has often to undergo the vexation of seeing every manœuvre of his subjected to the comments of those unaware of the hundreds of things he has to take into consideration besides the law of storms, and who were comfortably ensconced in their houses while he was experiencing the typhoon with its fierce gusts, interrupted by the, if possible, more ominous lulls, during which he cannot see three ship's lengths before him, the mountainous waves in which his good ship is but a "cock-boat," the loudest shouting inaudible, drowned in the roar of the tempest, boats and everything movable having been washed overboard, rudder gone, and perhaps one of the masts thumping at her bottom, while the seas threaten at every moment to swamp the ship.

VI. The origin of a typhoon is not quite understood, but appears to be connected with an abnormally high temperature and humidity in some place in comparison with the neighbourhood. Over such a place the hot air expands, ascends, and is thereby cooled. But the heat liberated by the consequent condensation of water-vapour retards the rate at which it cools on rising in the atmosphere, and enables it to rise still further. When the air has risen to a high level, it effects there an increase of barometric pressure, in consequence of which the upper air is set in motion out towards the circumference of the area in question. Thus a fall in the barometer at the surface of the sea in the middle of the hot and damp region is effected, and the surrounding air is impelled in towards the centre. The motions inwards at the surface of the sea, and outwards at a high atmospheric level, are, of course, contemporaneous, and one is assisted by the other. But air in motion is deflected towards the right in the northern hemisphere, owing to the rotation of the earth, except at or very near the equator; whence typhoons do not exist in that locality, for if the wind continues to blow into the depression it is soon filled up. Owing to its deflection towards the right, the wind is caused to move in a curved path in towards the centre, and the centrifugal force, developed in the curvilinear motion, deflects it still further from the straight line leading into the centre. The friction between the wind and the greatly disturbed sea-surface likewise retards the entrance of the air at the sea-surface into the central parts of the depression. But the air at a higher level in the atmosphere is subject to little friction, and escapes therefore at a greater speed from the central high-pressure area at that level. It is, therefore, apparent that once a cyclonal motion is started under circumstances favourable for its continuation, it tends to increase and to spread outwards.

There is, however, this important difference between a typhoon and a tornado, that the latter is taller than it is broad, whereas a typhoon perhaps does not reach above an altitude of four miles, while its horizontal diameter may amount to upwards of a thousand miles. Moreover, it is not at all likely that the centre at a higher level lies vertically above the central calm at the earth's surface, or even that the centres at different altitudes are situated in a straight line. We are, therefore, scarcely entitled to speak of an axis in a typhoon.

The spirals described by the air particles approaching the centre in a typhoon are known as logarithmic spirals, but unless a typhoon is stationary, which is perhaps never the case in Nature, new portions of air are constantly set in motion in front of the centre and others left behind by the typhoon.

As already remarked, the progressive motion of typhoons is evidently caused by the wind prevailing, if not at the surface of the earth, at any rate at a higher level. That the principal part of the disturbance is situated high above the surface of the earth is proved by the fact that the centres of typhoons pass across mountains several thousand feet high, and also by the circumstance that the difference between the temperature at the Hong Kong Observatory and at Victoria Peak is not perceptibly affected by the approach of a typhoon, for we cannot very well assume that the temperature of a vertical column of air is lower near the centre than outside the cyclone. The mountains referred to are situated on islands, and while crossing them the typhoon derives its store of water-vapour from the surrounding sea, for as soon as the centre has entered the coast, and is on all sides surrounded by dry land, it ceases to exist as a tropical storm, and can only be traced in the registers through a slight fall in the barometer, a freshening of the wind, perhaps amounting to a moderate gale at stations crossed by the centre, and wet weather. Inland in China the bull's eye of a typhoon does not appear to be observed.

As the wind blows more straight into the centre the nearer the equator you are, it follows that more air enters the typhoon from the southern semicircle than from the northern, and this is one of the reasons why typhoons nearly always move in a northerly direction. Moreover, the difference increases together with the dimension of the typhoons, which explains why they expand and accelerate their progressive motion at the same time.

The foregoing observations contain the principal practical results of investigations of about forty typhoons, continued during a period of three years. The mariner into whose hands this article may fall is advised to determine for himself the direction in which the centre of a typhoon, which he is experiencing, is travelling; for although typhoons of the classes enumerated are by far the most common, he never can be quite sure that he has not to do with an exceptional case, and quite possibly a case that is not found among the forty typhoons referred to above. By the time that we shall be in possession of full and trustworthy investigations of a couple of hundred typhoons, we may expect to have complete lists of the sub-classes of the four classes of typhoons, and to be better acquainted with cases of rare occurrence, for, after all, the typhoons are of a simpler construction and their paths more regular than is the case with storms in Europe. Typhoons are so violent near their centre that the whole disturbance is evidently ruled thereby, whereas storms in the North Atlantic and in Europe appear to be made up of a lot of local eddies, some of which are by degrees detached from the chief disturbance and form subsidiary depressions. The writer has not been able to ascertain the existence of a subsidiary depression in the China Seas during the last three years, and it is therefore doubtful whether such ever occur.

A great advance in our knowledge of typhoons in the China Sea will no doubt follow on the construction of a lighthouse on the dangerous Pratas Shoal, such as has for many years been talked about. Our storm-warnings would gain still more in value, and the cost of construction need not exceed the loss caused by a single disastrous typhoon.

EARTHQUAKE IN SIERRA LEONE

THE following correspondence has been forwarded for publication by Mr. R. H. Scott, F.R.S., Secretary, Meteorological Office:—

Government House, Sierra Leone, October 29, 1886

SIR,—I have the honour to transmit a copy of a communication received from Mr. J. M. Metzger, Manager of the Western District, in which he reports that an earthquake was felt at Sennehoo, in the Bompeh River, about the middle of last month.

(2) In the third and fourth paragraphs of his letter, Mr. Metzger draws attention to the fact that the shock in question was almost simultaneous with those experienced in other quarters of the globe, and that the latitude of the Bompeh District is within a few degrees of Charleston, America, where their effects lately proved so disastrous.

I have, &c.,
(Signed) J. S. HAY,
Administrator-in-Chief

The Right Hon. Edward Stanhope, M.P.,
&c., &c., &c.

I HAVE the honour to state, for the information of His Excellency the Administrator-in-Chief, that on the return of the District boat from the Bompeh River on the 16th inst., the coxswain reported that he had been informed at Sennehoo that about the middle of last month an earthquake was felt at that place and in the upper parts of the country; in consequence of which, many of the natives, who interpreted the event as prognostic of coming war, hastened down to the water-side to procure arms and powder in preparation for hostilities, which they regarded as imminent.

(2) The shock is said to have been continuous, accompanied with a rumbling noise as of some heavy-laden cart being moved along, resulting in the cracking and falling down of the mud plaster on the walls of the houses at Sennehoo. What happened in the upper parts of the country is, of course, not known, but the force must have been sufficiently severe to impress the people and influence them as they appeared to have been.

(3) It is remarkable that these vibrations, which seemed to have been extensive throughout the Bompeh District, and which seemed to have been so distinct, are almost simultaneous with those experienced in some places in the Mediterranean Sea, in Greece, and notably at Charleston, on the Atlantic coast of America, where their effects were so disastrous.

(4) The Bompeh, like the Ribbee and Cockborough Rivers, runs into Yawry Bay, which is an arm of the Atlantic, and the Bompeh District, on the eastern side of this ocean, is opposite to, and not many degrees of latitude below, the scene of the late disasters in America.

(5) I think it my duty to make this communication, as the information might possibly be of use to scientists engaged in the study of the facts connected with the range and transmission of these seismic disturbances.

(Signed) JOS. M. METZGER, Manager
Kent, Western District, October 20, 1886

SCIENTIFIC SERIALS

American Journal of Science, November.—The higher oxides of copper, by Thomas B. Osborne. The oxides here dealt with are copper dioxide and copper sesquioxide; but being unable to continue the subject, at least for some time, the author publishes the incomplete results so far obtained, in the hope that they may be of use to others wishing to continue this line of investigation.—The structure of the Triassic formation of the Connecticut Valley, by William Morris Davis. It is shown that disturbance has taken place after the period of deposition; that it was not caused by overflow or intrusion of trap-sheets; that it was not a simple monoclinal tilting; and that there is evidence for occurrence of unseen faults. The probable character of the disturbing force, its action on the fundamental schists, with consequent monoclinal faulting of overlying Triassic strata, and generally the area and depth of the disturbance, are questions also discussed in this elaborate paper.—Researches on the lithia micas, by F. W. Clarke. Descriptions and exhaustive analyses are given of the lepidolites of Rumford, Hebron, Auburn, and other parts of Maine, and of the iron-lithia micas of Rockfort granite-quarries near Cape Ann, Massachusetts.—The thickness of the ice in North-Eastern Pennsylvania during the Glacial epoch, by John C. Branner. So far from rising only 2200 feet above sea-level, as hitherto supposed, the ice is shown to have covered the twin peaks of Elk Mountain (2700 and 2575 feet), and no doubt also the Sugar Loaf, Ararat, and the other loftiest summits of this region during the Glacial epoch. A sheet of ice 1500 feet or less in thickness could never have flowed across such a mountainous region, so regardless as the great glacier was of its marked topographical features.—On the time of contact between the hammer and string in a piano, by Charles K. Wead. Owing to the uncertainty attending the theory developed by Helmholtz regarding the action of the hammer on a piano-string, the author has attempted to measure directly the time of contact by a simple process with results here tabulated.—Photographic determinations of stellar positions, by B. A. Gould. This is a reprint of the paper presented at the late Buffalo meeting of the American Association, and containing a brief history of stellar photography, and of the results so far obtained by the author in this department of practical astronomy.—Lucasite, a new variety of vermiculite, by Thomas M. Chatard. A description and full analysis is given of this substance, specimens of which have been found associated with corundum at Corundum Hill, Macon County, North Carolina. It has been named lucasite in honour of Dr. H. S. Lucas, so well known in connection with the Chester emery mine, Massachusetts.—Crystallographic notes, by W. G. Brown. An account is given of certain artificial copper crystals, of artificial crystallised cuprous oxide (cuprite), and of crystallised lead carbonate (cerussite) found under circumstances here described.—On the chemical composition of ralstonite, by S. L. Penfield and D. N. Harper. A comparative table is given of the analyses made by Nordenskjöld, Penfield, and Brandle of this rare mineral, which was found associated with thomsenolite at Arksuk Fjord, Greenland.—Analyses of the thomsenolite by the same chemists.—Mineralogical notes, by Edward S. Dana. Descriptive analyses are given of columbite from Standish, Maine, of diaspore from Newlin, Pennsylvania, of zincite from Stirling Hill, New Jersey, and of some native sulphur from Rabbit Hollow, Nevada, interesting because of its complex crystalline form.

Rivista Scientifico-Industriale, October.—On the cause of the magnetic rotatory polarisation, by Prof. Augusto Righi. Fresnel's hypothesis having been proved inadequate by recent experiment, the author has resumed the subject, with the view of ascertaining whether it may be explained by the reflected or transmitted vibrations of bodies endowed with rotatory power. If the incident polarised ray on penetrating a body is really decomposed into two inverse circular rays endowed with different velocities, the intensity of the two rays must also vary both in the reflected and transmitted light. The ray possessing greatest velocity of propagation, and consequently a lower index of refraction, must possess least intensity in the reflected and greatest in the transmitted light, assuming the two indices to be greater than unity, as in the opposite case the result would be reversed. Hence both the reflected and transmitted ray will become elliptical; and Prof. Righi has succeeded in determining this ellipticity by employing iron, the body endowed with the greatest rotatory power. The elliptical vibration of the reflected ray is in the opposite direction to that of the magnetising current, while that of the transmitted ray is in the same direction. In a future communication it will be shown that this agrees with the hypothesis of double circular refraction.—On the tests of fatty substances, and especially of olive oil, by Professors G. B. Bizio and L. Gabba. This paper contains a critical inquiry into the methods of testing the purity especially of olive oil, and it concludes that none of the processes now in use are absolutely trustworthy. Even that of Bechi fails to distinguish with certainty between olive and cotton oil.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, November 18.—"A Theory of Voltaic Action." By J. Brown. Communicated by Lord Rayleigh, Sec.R.S.

The difference of potential near two metals in contact is due to the chemical action of a film of condensed vapour or gas on their surfaces. Such a pair of metals is thus similar to a galvanic cell with its electrolyte divided by a diaphragm of air or other gas; and it is the difference of potential of the films that is measured in "contact" experiments; the metals themselves being at one potential.

Experiments with an electrometer having quadrants of the metals under examination, the construction of which was described, were made on the rate of decrease of the difference of potential near two metals in contact, and exposed to the action of the air and of other gases; also where a change in the constituents of the atmosphere surrounding a pair of metals in contact reverses the difference of potential near them in correspondence with the reversal of electromotive force which takes place after a similar change in the corresponding liquid electrolyte used with the same metals as a voltaic cell.

Such reversal takes place with pairs of copper-iron when hydrogen sulphide gas, or ammonia gas, is added to the air surrounding them; with silver-iron, when hydrogen sulphide is added; and with copper-nickel when either ammonia or hydrochloric acid gas is added.

Neutral or inert gases have little or no effect.

Covering the metals with varnish, or immersing them in naphtha, to protect them from atmospheric action, reduced the difference of potential near them considerably, but not to zero.

Drying the atmosphere about a copper-zinc pair by means of phosphoric anhydride in one instance reduced the difference of potential in 173 days from ·66 to ·5 Daniell. Then, on opening the instrument, it rose to ·67 Daniell.

A permanent current was produced by placing the (apparently) dry plates of copper and zinc in close proximity, so that their films were in contact. When the plates were either brought into actual metallic contact, or separated farther apart than a certain distance, as stated the current ceased. This "film-cell" could also be polarised by sending a current through it from another battery.

Modifying an old experiment, due to Gassiot, so as to avoid any contact of dissimilar metals, it was shown that, when the zinc plate of the volta condenser was joined to the zinc quadrant of the electrometer and the copper of the condenser to the copper of the electrometer, on altering the capacity of the condenser an alteration of the difference of potential near the quadrants was produced.

In an appendix, Mr. J. Larmor, of St. John's College, Cambridge, points out the difficulty of explaining this last experiment by any hypothesis other than that of some kind of chemical action at the surface of the metals.

November 25.—A paper by Sir Richard Owen, F.R.S., was read, of which the subject was a fossil lower jaw of the large extinct marsupial quadruped which the author, from previous fragmentary specimens, had referred to a carnivorous pouched species of the size of a lion, to which was assigned the generic name *Thylacoleo*, and the probable prey of which had been the larger forms of herbivorous marsupials, which, with their destroyer, had become extinct.

Several species, allied to the kangaroo, but equalling respectively in bulk a rhinoceros, an ox, an ass, had become extinct. The largest existing kind, to be seen in the Zoological Gardens, was named by Dr. Shaw, *Macropus major*. It has escaped extinction by its swiftness and power of concealment in the "scrub." Wombats, also, of the size of fallow-deer, co-existed with the huge kangaroos; the small kinds, capable of concealing themselves in burrows, alone survive.

Remains of the large extinct marsupials, both devourers and prey, are to be seen in the Geological Department of the Museum of Natural History; they are described and figured in the author's work on "Fossil Marsupialia." Their extinction is attributed, with that of the wolf-like *Cynocephalus* and the *Thylacoleo*, to the aboriginal natives of Australia.

Linnean Society, November 18.—W. Carruthers, F.R.S., President, in the chair.—Mr. H. Bury was elected a Fellow of the Society.—Mr. W. H. Beeby showed specimens of *Callitriche truncata*, Gussone, from near Westerham, Kent. The species had long been supposed to be extinct in this country, being only known as British from dried specimens from Sussex in Borrer's Herbarium.—Mr. D. Morris exhibited two enlarged photographs of the Castilloa Rubber-tree of Central America (see *Trans. Linn. Soc.* Botany, 2nd ser. vol. ii. part 9). The larger photograph illustrated the manner in which trees were treated to extract rubber, by a special cut from above downwards. Trees of ten years old and upward are said to yield about eight gallons of milk at the first bleeding. This milk is coagulated by the use of the juice of *Calonictyon speciosum*, and the rubber prepared by washing and pressing. Mr. Morris described the habit and growth of the trees in their native forests, and expressed the opinion that for cultural purposes this rubber-tree may be better suited to the circumstances of planters than any other. It could be utilised as a shade tree in cacao and coffee plantations, and yield at the end of ten years at the rate of twenty shillings per tree in marketable rubber. In British Honduras trees are tapped for rubber every three or four years.—Mr. A. D. Michael exhibited living specimens and preparations of an *Argas*, received from Mrs. Crawford, the State Entomologist of Adelaide, Australia. The insects in question appear to be identical with the much-dreaded *Argas persicus*, Fischer, the bite of which was supposed to cause madness and death.—Mr. H. N. Ridley made remarks on specimens in spirit and drawings of species of *Coryanthes*, viz. *C. macrantha*, Hook., and *C. maculata punctata*. He mentioned that Mr. Rodway, of Demerara, had lately published observations showing that the statement of Crüger, hitherto believed, as to the fertilisation by bees, did not obtain in all the species; inasmuch as in *C. speciosa* he (Mr. Rodway) had noticed that a kind of green fly was the fertiliser.—Mr. Geo. Murray exhibited specimens of *Rhipilia* in spirit from Grenada, West Indies, obtained at a depth of five fathoms.—Mr. W. Fawcett, exhibited coloured drawings of *Hydnora abyssinica* and *H. bogosensis*, sent by Signor Beccari from Florence. They clearly showed the difference between the two species, in colour, and in the former having a book-like process below the apex, and its ramentiferous surfaces have long ramenta at their margins. Both species differ from *H. africana* in the ramentiferous surfaces not extending to the apex.—Mr. C. T. Musson drew attention to a branch of a blackthorn, obtained near Newark, showing a curious malformation of the branchlets. — Dr. Maxwell Masters read a paper on the peculiar conformation of the flowers of *Cypripedium*. The explanation may be sought in the course of development, in the minute anatomy and arrangement of the fibro-vascular bundles, and in the examination of the comparative morphology of the flower; organogeny affords in this case only doubtful testimony, as the flower is irregular from the first. The distribution of the primary fibro-vascular bundles, and of the offshoots from them, affords more conclusive evidence of the true construction of the flower, and if studied in conjunction with the comparative morphology leads to very satisfactory results. By these means it becomes easy to refer the flower to the ordinary type seen in a regular pentacyclic and trimerous monocotyledon, and from which it is reasonable to infer it may have originated. The deviations from the type have arisen from concrescence or inseparation of some parts, inordinate development of others, and complete suppression of a third series. The author cited instances showing numerous intermediate gradations between the ordinary conformation of *Cypripedium* and that of the ideal type trees, proving that what was, at first, a matter of speculation and inference from imperfect evidence, was borne out by actual facts. The illustrations brought forward afforded examples of the reduction of parts and the increased number of parts, in connection with which the author alluded to the special tendency to develop the second or inner row of stamens, as happens in Restiaceæ and Xyridaceæ, while in Iridaceæ the opposite tendency is manifested. Another series of illustrations comprised cases of regular and of irregular *Peloria*, which were of special importance as affording evidence on the one hand of the probable past conformation of the flower, and on the other of the probable course of development in the future.—The fifth and concluding part of the Rev. A. Eaton's monograph of recent Ephemeridæ or may-flies was read. The author says 55 genera and 270 species have been characterised, in addition to 11 nymphs and 19 species of doubtful position; 5 genera and 68 species are new to science.—Mr. J. G. Baker read a paper entitled "Further Contributions to the Flora of Madagascar," in which upwards of 250 new plants, seven of them new genera, gathered recently by the Rev. R. Baron, F.L.S., are described. Of the new genera, one belongs to Menispermaceæ, one to Geraniaceæ near *Impatiens*, one to Rubiaceæ, and two each to Melastomaceæ and Compositæ. Of well-known Cape types, *Pelargonium*, *Stoebe*, *Cineraria*, and *Belmontia* are now for the first time added to the Madagascar flora. The faint affinity of the flora of Madagascar to that of India and Malaya is strengthened by the discovery of the genus *Cyclea*, and of new species of *Alyxia*, *Didymocarpus*, and *Strobilanthes*. Of types of economic interest there are new species of *Dalbergia*, *Macaranga*, *Strychnos*, *Balsamodendron*, and *Garcinia*. It seems that during the last ten years between 1100 and 1200 new plants from Madagascar (29 of which are new genera) have been described in the *Journal* of the Linnean Society and *Journal of Botany*, nearly all of them collected by our own countrymen.

Chemical Society, November 18.—W. Crookes, F.R.S., Vice-President, in the chair.—The following papers were read:—Researches on the relation between the molecular structure of carbon compounds and their absorption-spectra; part 8, a study of coloured substances and dyes, by W. N. Hartley, F.R.S.—Spectroscopic notes on the carbohydrates and albumenoids from grain, by W. N. Hartley, F.R.S.—Preliminary note on the electrolysis of ammonic sulphate, by Herbert McLeod, F.R.S.—The preparation and hydrolysis of hydrocyanides of the diketones, by Francis R. Japp, F.R.S., and N. H. J. Miller, Ph.D.—The action of salicylic aldehyde on sodium succinate in presence of acetic anhydride, by Gibson Dyson.—The reduction of nitrites to hydroxylamine by hydrogen sulphide, by E. Divers, F.R.S., and T. Haga.—Note on some double thiosulphates, by J. B. Cohen, Ph.D.—Preliminary note on the action of triphenylmethyl bromide on ethyl sodio-malonate, by George G. Henderson, M.A., B.Sc.—Action of silicon tetrachloride on aromatic amido-compounds, by Arthur Harden, B.Sc.

Physical Society, November 27.—Prof. W. G. Adams in the chair.—The following papers were read:—On a method of measuring the coefficient of mutual induction of two coils, by Prof. G. Carey Foster, F.R.S. The two coils are for convenience designated by P and S (primary and secondary). The method as originally devised consists of two parts: (1) observing the swing of the needle of a galvanometer placed in series with the secondary coil when a current of strength γ is started in the primary; (2) placing the galvanometer and a condenser of known capacity, c, as a shunt between two points, A and B, of the primary circuit, such that the first swing of the galvanometer needle on completing the primary is the same as in (1). It is easily seen that under these conditions $M = crr_1$, where M is the coefficient to be determined, r = resistance between the points A and B, and r_1 = resistance of galvanometer and secondary coil. The method requires the value of γ to be the same in the two experiments, and facilities for varying r without altering γ. To overcome these difficulties the arrangement has been modified so as to make it a null method. The connections remain the same as in (2), excepting that the ends of the secondary coil are connected to the terminals of the galvanometer through a variable resistance with no self-induction. If p be the resistance of the secondary coil and variable resistance when adjusted, so that, on completing the primary circuit, the integral current through the galvanometer is zero, it is shown that $M = cpr$, where c and r have the same meaning as before. For let A and E be the potentials of the galvanometer terminals at any time, t, q the resistance of galvanometer, y the current through it, and N and L the coefficients of self-induction of the galvanometer and secondary coil respectively. Then considering the path from A to E through the secondary coil we have—

$$A - E = px + L\frac{dx}{dt} - M\frac{d\gamma}{dt}.$$

For path through galvanometer—

$$A - E = qy + N\frac{dy}{dt}.$$

Equating these, and integrating from $t = 0$ to $t = \infty$, we get—

$$p\int_0^\infty xdt - M\gamma = 0.$$

Since $\int_0^\infty xdt$ = charge of condenser,

$$= c\gamma r,$$

we see that $$M = cpr.$$

It is easily shown that if $L = M$ then $A - E = 0$ for all values of t. Hence the galvanometer might in this case be replaced by a telephone. By inversion, the method could be used for determining the capacity of condensers in absolute measure if M be known. The author thinks the method will be useful for dynamo-machines, and gave a series of numbers obtained by experiments on different coils, showing that it gives consistent results. Mr. C. V. Boys suggested that, by arranging a switch to change the connections from (1) to (2) in rapid succession, a steady deflection might be obtained, and thought that this would enable very small coefficients to be determined. Remarks by Prof. Forbes, Prof. Adams, and Prof. Perry were answered by Prof. Foster and Dr. Fison.—On the critical mean curvature of liquid surfaces of revolution, by Prof. A. W. Rücker, M.A., F.R.S. The paper is chiefly mathematical, and deals with liquid surfaces of revolution attached to two circular rings, the planes of which are at right angles to the line joining their centres. By "mean curvature" the author designates *half the sum of the reciprocals of the two principal radii of curvature of the surfaces.* Maxwell has shown in his article on "Capillary Action" ("Encyclopædia Britannica"), that, if the film be a cylinder, a slight bulge will cause an increase or decrease in the mean curvature according as the length is $<$ or $>$ $\frac{\pi}{2}$ times the diameter. If $l = \frac{\pi}{2}d$, then a small change in the volume of the surface will modify its form, but will not alter the mean curvature. Thus the mean curvature of such a cylinder is evidently a maximum or minimum with respect to that of other surfaces of constant mean curvature, which pass through the same two rings at the same distance apart, and which differ but little from the cylindrical form. Hence the cylinder may be said to have a *critical mean curvature* when the distance between the rings is $\frac{\pi}{2}$ times their diameter. If the distance between the rings is altered, a similar property is possessed by some other surface. The author's paper investigates the general relation between the magnitude and distance apart of the rings, and the form of the surfaces of critical curvature. If x is the axis of revolution, then the equation to a liquid surface of revolution is given by the expressions—

$$x = \alpha E + \beta F, \qquad y^2 = \alpha^2\cos^2\phi + \beta^2\sin^2\phi,$$

where F and E are elliptic integrals of the first and second kinds respectively, of which the amplitude is ϕ, and the modulus $K = \sqrt{\alpha^2 - \beta^2}/\alpha$ as usual, $\Delta = \sqrt{1 - K^2\sin^2\phi}$, whence $y = \alpha\Delta$, and if $K = \sin\theta$, then $\beta = \alpha\cos\theta$, and since $\alpha > \beta$, α and β are the maximum and minimum ordinates. The results show that as θ increases from 0° to 90°, the surface of critical mean curvature is an unduloid with limits of cylinder and sphere, when $\theta = 0°$, and $\theta = 90°$ respectively. When θ passes from 90° to 180°, the surface is a nodoid with limits of sphere and a circle whose plane is perpendicular to the surface of revolution. In the third quadrant the surface is still a nodoid the limits of which are a circle and the catenoid. Finally, in the fourth quadrant the surface is an unduloid, the limits being the catenoid and cylinder. Experiments were shown proving that with cylindrical films, where $l < \frac{\pi}{2}d$, increase of internal pressure produced a bulging, whereas if $l > \frac{\pi}{2}d$, a bulging was produced by decrease of pressure. From this it is evident that if the interiors of two cylindrical films, whose $l < \frac{\pi}{2}d$, be connected, stable equilibrium will result, whereas if $l > \frac{\pi}{2}d$, there will be unstable equilibrium. These facts were illustrated experimentally with great success. After some remarks by Mr. C. V. Boys, the proceedings terminated.

Anthropological Institute, November 23.—Francis Galton, F.R.S., President, in the chair.—The election of Mr. C. W. Rosset as a Corresponding Member was announced.—Prof. A. H. Keane read a paper, by Consul Donald A. Cameron, on the tribes of the Eastern Soudan.—The Assistant Secretary exhibited, on behalf of Mr. J. Olonba Payne, nine symbolic letters (Aroko) as used by the tribe of Jebu in West Africa.—The Secretary read a paper, by Mr. T. R. Griffith, on the races inhabiting Sierra Leone.—The Rev. George Brown gave a brief *résumé* of his paper on the Papuans and Polynesians, the reading of which was adjourned till the next meeting.

PARIS

Academy of Sciences, November 29.—M. Daubrée in the chair.—The medal prepared by the youth of France to commemorate the centenary of M. Chevreul, was presented to the President of the Academy, with some appropriate remarks by M. de Quatrefages. The medal, which is a fine work of art by M. Roty, bears on one side a bust of the illustrious *savant*, and on the reverse his full figure, seated in an armchair, in an attitude of study, with the legend "La Jeunesse française au Doyen des Étudiants, 31 Août, 1786—31 Août, 1886." After defraying the expenses of this and another medal of smaller size, a copy of which will be supplied to all subscribers, the Committee has a large balance in hand, which it proposes to utilise by issuing a complete *Catalogue raisonné* of M. Chevreul's works.—Remarks on the 210th volume of the *Connaissance des Temps* (for 1888), presented to the Academy by M. Faye.—A contribution to the history of the decomposition of the amides by water and the diluted acids, by MM. Berthelot and André. These studies have been undertaken for the purpose of better determining the degree of stability, in presence of the acids, of some typical amides, which play an essential part in the tissues of organised beings, such as urea, asparagine, and others.—Glycose, glycogene, and glycogeny, in relation to the production of heat and of mechanical power in the animal system, by M. A. Chauveau. In this second communication the author deals with combustion and the development of heat in the organs while at work. In this state of physical activity the quantity of glycose which disappears in the capillaries is increased, and is in proportion with the excessive activity of the combustions excited by the play of the organs.—Fluorescences of manganese and bismuth, by M. Lecoq de Boisbaudran. In this preliminary paper three conditions are considered: (1) a single solid dissolvent and two active substances, each fluorescing with this dissolvent; (2) a solid dissolvent and two active substances, of which one alone fluoresces with the dissolvent; (3) two solid dissolvents and one active substance fluorescing with each of the dissolvents.—Treatment of the grape-vine with the salts of copper against mildew, by MM. Crolas and Raulin. Quantitative analyses are given of the amount of copper detected in the products of vines treated by this process. Although the actual quantity is never really dangerous, special precautions are recommended in all cases where the grape is intended for consumption.—On the phosphates and arseniates of silver, by M. A. Joly. The precipitated triargentic phosphate, PO_8Ag_3, obtained by double decomposition, is shown to be amorphous, easily dissolving in phosphoric acid even at a low temperature. The limits are determined within which the concentration of the phosphoric solution should be varied in order to obtain at pleasure the crystallised triargentic phosphate or the diargentic phosphate, PO_8Ag_2H.—On some coloured reactions of the titanic, niobic, tantalic, and stannic acids, by M. Lucien Lévy. Some new specific characters of these acids are described, the reagents employed being substances which nearly always present a phenolic function. Hence reciprocally these latter may in their turn be characterised by the same mineral acids.—On the conditions favourable to the restoration of the elements of the transparent cornea, by M. Gillet de Grandmont. These conditions are shown to be suppression of the suppuration, absolute repose, and absence of all intervening irritation.—On a process for intensifying the normal virulence of the microbe of symptomatic charbon, and restitution of the original activity after attenuation, by MM. Arloing and Cornevin.—Note on some essays in antituberculous vaccination, by M. Vittorio Cavagnis. These experiments were made according to M. Pasteur's method, on some rabbits and guinea-pigs, with but partial success. The author is now endeavouring to ascertain whether this method of vaccination is at all applicable to tuberculosis.—On the conformation of the external reproductive organs in the female of the anthropoid apes of the genus Troglodytes, by M. A. T. de Rochebrune.—Observations on the continuous blastogenesis of *Botrylloides rubrum* (Milne-Edwards), by M. S. Jourdain.—New methods of preparing the crystallised carbonates, by M. L. Bourgeois.—The Uralian Society of Naturalists informs the Academy that it is organising at Ekaterinburg, Russia, a Scientific and Industrial Exhibition for Siberia and the Ural Mountains, which will be opened on May 15/27, 1887, and closed on September 15/27 following.

STOCKHOLM

Academy of Sciences, November 10.—On a recently discovered map of Scandinavia and parts of the North Atlantic, edited, in 1539, by Olaus Magnus, a Swedish Catholic clergyman, by Baron A. E. Nordenskjöld.—On the mineral thorite, from two new localities, by the same.—On the Quaternary strata of the Isle of Gothland, by Herr H. Munthe.—On the development of bi-periodic functions in the series of Fourier, by Dr. C. Charlier.—Contributions to the knowledge of the infloration and fructification of the Scandinavian alpine plants, by Dr. C. Lindman.

CONTENTS

THURSDAY, DECEMBER 16, 1886

THE PALISSY OF CALICO-PRINTING

The Life and Labours of John Mercer, F.R.S. By Edward A. Parnell. (London: Longmans and Co., 1886.)

THE subject of this memoir was one of the most remarkable men of his time. A son of the soil, and almost wholly self-taught, he effected what was practically a revolution in one of our staple industries by his discoveries in technical chemistry and by his application of chemical principles to the dyer's art. With no laboratory training other than that which he gave himself, he by his skill and sagacity as an experimentalist added enormously to the resources of a great industry: owing nothing to academies, and uninfluenced by schools of learning, he made himself master of the chemical philosophy of his time, and by the acuteness and originality of his speculations he has permanently influenced the development of theoretical chemistry. In Lancashire, the scene of his work, the name of John Mercer is held in hardly less esteem than that of John Dalton; and probably to many people in Cottonopolis the director of the Oakenshaw Print-Works was a far more important personage than the old Quaker in George Street, who gave lessons in the *New System of Chemical Philosophy* at the rate of half-a-crown an hour. The Atomic Theory has doubtless contributed much to the intellectual greatness of Manchester, and Manchester men are not ungrateful: they have named one of their streets after its illustrious author. Still calicoes and calico-printing are what they have to live by, and although they have not yet, so far as we know, named a street after John Mercer, they have shown, by the widespread adoption of his processes, a very practical appreciation of the value of his labours.

John Mercer is the Palissy of calico-printing. Not that there was anything in the least degree tragic in the life of the Lancashire dyer; his career was one of almost uninterrupted success, and his domestic peace was unclouded. But he had the great potter's indomitable will and fixity of purpose; his unwearied patience and unremitting industry. Both men had the same high ideal of their art and the same contempt for false work. Each began his life at the bottom rung of the social ladder, and each found his life's work in a direction other than that in which he set out. Both were men of strong religious feeling, and both left the faith of their forefathers in compliance with the dictates of principle, but with this difference, that whilst the Huguenot artist found the Bastille and death, John Mercer could build his Sunday-schools in peace and quietness, and find contentment in a standard of doctrine which Mr. Matthew Arnold has characterised as the product of a mind of the third order.

John Mercer was born on February 21, 1791, at Dean, near Blackburn. His father was originally a hand-loom weaver, but the development of the factory system had led him to take to agriculture. He died when the son was barely nine years old, and John was set to work as a "bobbin-winder." A pattern-designer belonging to the Oakenshaw Print-Works, in which Mercer was destined to play so considerable a part, gave him his first lessons in reading and writing; and the Excise-surveyor at the same works (it was in the days when each square yard of printed calico paid an Excise duty of threepence) taught him the elements of arithmetic. He soon became noted for his aptitude at figures, and later on for his skill in music; and for a time he found a congenial exercise for his artistic faculty in the band of a militia corps. Music remained a passion with him throughout his life, and although, we are told, a man of great self-possession, he was sometimes entirely overcome by it. Mercer was sixteen years of age, and had settled down apparently to the work of a hand-loom weaver, when a very slight incident—as slight as that which made Palissy a potter—gave an entirely new direction to his thoughts. His mother, it appears, had married again. Visiting her one day, John was so much struck with the orange colour of the dress of his little step-brother on her knee, that, to use his own words, he "was all on fire to learn dyeing." He had no means of obtaining instruction: he had no book on the subject, nor could he procure any receipts. He found, however, that the dyers of Blackburn, some five miles distant, obtained their materials from a certain druggist in that town. Mercer repaired to him, and requested to be supplied with materials for dyeing. "What do you want?" inquired the shopman. "I can't tell you," replied John; "will you tell me the names of all the different materials you sell the dyers here?" "Oh, I sell them peach-wood, Brazil-wood, logwood, quercitron, alum, copperas, and others," mentioning their names. Mercer reckoned his money, and found he could afford threepence for each dye-stuff. Armed with these articles he returned home, "full," as he says, "of dyeing and dyeing materials." He seems to have been fortunate in obtaining the use of a convenient place for his experiments, where he had all the necessary apparatus for small trials. Here he commenced entirely by "rule-of-thumb"; but by industry and close observation he acquired considerable knowledge of the properties of dye-stuffs, and ascertained the methods of dyeing in most of the colours then in vogue.

To become a dyer was now the dominant idea of Mercer's life. Everything comes to him who waits, and fortunately for Mercer, as it seemed at the time, he had not to wait long. The Messrs. Fort, the proprietors of the Oakenshaw Print-Works, heard of the success of his dyeing experiments, and offered him an apprenticeship in the colour-shop of their factory. It was one thing to get inside a colour-shop and quite another to get any information there. No workmen are more jealous of their *arcana* than the foremen of colour-shops: their knowledge even to-day is almost entirely empirical, and their secrets are invested with a degree of mystery which is frequently ludicrously disproportionate to their value. After ten months' irksome labour Mercer's indentures were cancelled. The Continental disturbances of 1810 reacted disastrously upon all industries connected with the cotton manufacture, and the "Berlin decree," which led to the destruction of all printed calicoes and other goods of English manufacture then in bond in certain European States, was severely felt by the Lancashire printing establishments. Mercer was forced for a time to abandon the calling of a colour-mixer, and to return to his work at the hand-loom. But his brains were still among his colour-pots. It was characteristic of the man, that, being in Blackburn to procure a marriage license, he should be led to a secondhand bookstall in the market-place to search for printed matter relating to his favourite art. At a time when Mary Wolstenholme might properly consider him as more anxious about the *res angusta domi*, he was engaged in negotiating the purchase of "The Chemical Pocket-Book; or, Memoranda Chemica, arranged in a Compendium of Chemistry, by James Parkinson, of Hoxton." This book, together with "The Tables of New Nomenclature, proposed by Messrs. De Morveau, Lavoisier, Berthollet, and De Fourcroy, in 1787," opened out a new world to him. He had, at the very outset of his trials, convinced himself that it was only by a thorough knowledge of the properties of dyeing materials, and of their behaviour under varying conditions, that the operations of the dyer can be intelligently carried on: he now saw that all this knowledge must primarily depend upon chemical science, and that it was on chemistry that the extension of his art must ultimately rest. This view of the relations of science to practice strengthened with Mercer's experience. Years afterwards, when he had attained to fame, he was called upon to express his opinion concerning the necessity of technical education in this country. "I entirely concur with you," he wrote to a friend, "that for the preservation and benefit of the British arts and manufactures, the masters, managers, and skilled artisans ought to be better instructed in the *rationale* and scientific principles involved in their operations. Chaptal remarked that 'practice is better than science' (*i.e.* abstract principles), 'but when it is necessary to solve a problem, to explain some phenomenon, or to discover some error in the complicated details of an operation, the mere artisan is at the end of his knowledge, he is totally at a loss, and would derive the greatest assistance from men of science.' Probably no person would, from his own experience, confirm the above remark, as regards the art of calico-printing, more heartily than myself." He observed that, "as regards good practical men, no district could excel Lancashire; but in all the processes, from the grey piece to the finished print, embracing thirty to forty operations, both the science and practical experience of the cleverest are requisite to keep all things straight and to detect the cause of, and rectify, mishaps. . . . An amusing volume might be written about ludicrous mistakes, and equally ridiculous attempts to rectify them."

Mercer's first important invention in calico-printing was made in 1817, and curiously enough it was in the application of a colour akin to that which had fired his ambition to become a dyer. He found in the alkaline sulphantimoniates an excellent medium for procuring a bright orange colour on cotton fabrics. Heretofore no good orange suitable for the use of the calico-printer was known. The best orange was made from a mixture of quercitron yellow and madder red, but it was difficult to adapt it to other colours in the styles then in demand. Mercer's antimony orange supplied the want: it was not only a fine colour in itself, but was capable of being combined and interspersed in a great variety of styles. This discovery led to his re-engagement at the Oakenshaw Works: after a seven-years' service he was admitted as a partner, having as a co-partner, for a while, Richard Cobden; and he remained connected with the firm until its dissolution in 1848, when he retired from business with a moderate fortune.

It would be difficult in the space at our disposal to do full justice to the many discoveries and improvements which Mercer introduced into the art of dyeing and printing. His skill and energy led not only to the invention of new styles and new colours, but to the development even of new branches of chemical industry. His application, for example, of chromium compounds practically created the manufacture of bichrome: when Mercer first began experimenting with this substance its cost was half-a-guinea an ounce; it is now produced by the hundreds of tons, and may be bought retail at less than sixpence per pound. Some of his processes are, of course, obsolete, but many are still in use: the "manganese bronze," for example, which he introduced in 1823, seems to re-appear about every ten years, and was in large demand some three or four years since. Mercer was an indefatigable experimenter: nothing is more extraordinary than his skill and inventiveness in the application of his new colours to the creation of fresh styles or novel combinations; his genius in this respect was almost kaleidoscopic.

One of the greatest improvements made by Mercer in the operations of the dyer was his introduction of the alkaline arseniates in what is called the "dunging" operation, the object of which is to remove that portion of the mordant which has not become insoluble and firmly attached to the fabric by the process of "ageing." The loosely-attached mordant, unless previously removed, would dissolve in the dye-bath, to the injury of the whites and the deterioration of the dyeing liquor. Of scarcely less importance was his method of preparing mixed cotton and woollen fabrics so as to enable the mixed fibres to acquire colouring-matters with equal readiness. His observation of the extraordinary facility with which certain "lakes," or compounds of alumina with organic colouring-matters, are dissolved by oxalate of ammonia led to the introduction of a method of using aluminous colour-precipitates in steam colour-work, which was extensively employed in the East Lancashire print-works. And lastly, his method of preparing stannate of soda was not only of service to the calico printer by greatly cheapening an indispensable agent, but was of considerable pecuniary benefit to himself.

Mercer's skill and knowledge were ungrudgingly given to the fellow-workers in his art, and he was constantly appealed to by the calico-printers and chemical manufacturers of Lancashire for assistance and advice. His acquaintance with the literature of the abstract chemistry of his time was very remarkable. He had indeed all the essential qualities and instincts of the scientific mind: there was a certain comprehensiveness about the man, a certain vigorous grasp of general principles, and a largeness of view which made his influence felt at once among men of science. There is no question that had Mercer devoted himself to pure science he would have attained hardly less distinction than he has secured as a technologist. His method of work was essentially scientific. Thus no sooner did he become acquainted with the doctrine of chemical equivalents than he had the strengths of his chemicals and reagents adjusted to a simple relation of their equivalents. Mercer indeed was one of the earliest workers in volumetric analysis; in 1827 he devised a method of valuing bleaching-powder and bichrome by means of standard solutions. His speculations on the nature of white indigo, on the constitution of bleaching-powder, and on the ferrocyanides and nitroprussides were much in advance of his day. His theory of catalysis, which he illustrated by many striking and original examples, was extended by Playfair, and has been subsequently worked out by Kekulé as the only satisfactory explanation yet given of a very remarkable and interesting group of phenomena. Graham's early experiments on the heat of chemical combination and the nature of solution induced Mercer to test the practicability of effecting the partial separation of different hydrates by some process of fractional filtration. These experiments, made from a purely scientific stand-point, resulted in the discovery of the mode of action of the caustic alkalies on cellulose, and led to the process which has come to be known as "mercerising," in which cotton fabrics are "fulled" by their contraction on treatment with caustic soda. Mercer appears to have been the first to notice the remarkable solvent action of an ammoniacal copper solution on cotton, which could be re-precipitated as almost pure cellulose by the addition of an acid. His habit of searching for first principles led him, as far back as 1854, to speculate on the relations among the atomic weights of the chemical elements, and the constitution of chemical compounds: he brought his views before the Leeds meeting of the British Association in 1858. He was an early worker on photography, and devised several modifications of the cyanotype process adapted to printing on cambric and similar fabrics.

Mercer was one of the original Fellows of the Chemical Society, and he was a juror of the Exhibitions of 1851 and 1862. In 1852 he was elected into the Royal Society. He died, ripe in years and rich in the contentment afforded by the retrospect of a well-spent life, on November 30, 1866. T. E. THORPE

THE BRITISH INTERNATIONAL POLAR EXPEDITION

Observations of the International Polar Expeditions, 1882–83: *Fort Rae*. 326 pp. 4to, and 29 plates. (London: Trübner and Co., 1886.)

AT the Polar Conference of Vienna in April 1884 it was declared to be very desirable that the results from all the circumpolar stations should be published by Christmas 1885. This time was not kept strictly by any of the parties. The first Report completed was that of Lieut. P. H. Ray, of the U.S. Army, for Point Barrow, which appeared early in 1886, and this has now been followed by the present volume, which came out in August last.

The other Expeditions, however, have not been idle, for several have issued portions of their Reports: *e.g.* the French for Cape Horn; the Russians for Sagastyr at the mouth of the Lena; and the Austrians for Jan Mayen; while quite recently the Germans have announced the publication of the results for their two stations—Cumberland Sound and South Georgia.

The British Expedition was from the outset at a serious disadvantage. It was not until April 2, 1882, that the definite sanction of the Government was obtained, and the party were obliged to sail from Liverpool on May 11 in order to catch the Hudson Bay Company's convoy from Winnipeg. Accordingly the time available for preparations and training was extremely short, and no special instruments could be made.

The party consisted of Captain (now Major) H. P. Dawson, R.A., with two sergeants and a gunner of the same service. The journey was prolonged and fatiguing, lasting three months and a half, and the Expedition only reached its destination at 10 p.m. on August 30. Only one day was thus available for unpacking, &c., before the regular hourly observations commenced.

The start for the return journey was made within three hours of the time of the final observation, and even then it was only owing to a fortunate shift of wind on Lake Athabasca, which opened the ice and allowed the boats to get through, that the party was able to reach Manitoba, with its baggage, in October. Otherwise the instruments must have been left behind for some months, as the Expedition must have completed its journey by sledge.

The observations have been discussed in strict accordance with the International scheme, the units employed being metric and centigrade. The magnetic discussions were carried out by Major Dawson in conjunction with Mr. Whipple. The meteorological work was intrusted to Mr. R. Strachan and Mr. John A. Curtis, of the Meteorological Office.

The magnetic observations are specially interesting, from the proximity of the station to the magnetic pole The disturbances were therefore of great frequency and violence, as will be seen from the plates to the volume. The auroral journal also affords a copious store of information on that subject.

The following few results, which we extract from the observations made by the Expedition, will be of interest to our readers:—

The barometer at Fort Rae varied between 771 mm. (30·35 inches) and 721 mm. (28·39 inches), with a maximum daily range of 24 mm. (0·94 inch), and the least of 0·7 mm. (0·03 inch).

The highest thermometer-reading recorded by the Expedition was 25°·6 C. (78°·1 F.), whilst the lowest was − 44°·6 C. (− 48°·3 F.) in the air, the terrestrial radiation instrument registering − 46°·7 C. (− 52°·1 F.).

On the coldest day experienced (January 3) the mean temperature of the twenty-four hours was − 41°·9 C. (− 43°·4 F.), whilst that determined for the hottest day (August 13) was 19°·9 C. (67°·8 F.), giving an extreme range of average daily temperature of 61°·8 C. (111°·2 F.).

The highest mean velocity of the wind recorded any day was 8·5 metres per second (19 miles per hour) from the north north-west.

The average magnetic declination at Fort Rae was 40° 20′ E., the extreme change observed in the diurnal range being 11° 25′. On the most quiescent day the angular motion of the needle was 0° 17′, both values largely exceeding movements observed in these latitudes.

The dip or inclination of the needle was 82° 55′, whilst the measured values of the total and horizontal magnetic forces were 0·62 and 0·08 electrical units respectively.

OUR BOOK SHELF

Natural History, its Rise and Progress in Britain, as developed by the Life and Labours of Leading Naturalists. By Alleyne Nicholson, M.D., D.Sc., Regius Professor of Natural History in the University of Aberdeen. British Science-Biographies. (London and Edinburgh: W. and R. Chambers, 1886.)

THIS little octavo volume of about 300 pages is a readable book, and accurate in its information as far as it goes. But, besides being sketchy—which is no doubt a fault incidental to the form of the series—it is strangely ill-balanced. In the first place, the author has travelled beyond the limits of his title by giving biographical sketches of Aristotle, Linnæus, Lamarck, and Cuvier—together constituting more than a third of the whole number of "British Science-Biographies" with which they are intermingled. In the next place, as regards the "British Science-Biographies" which are given, there is no proportion observable between the relative magnitudes of these British biologists and the amount of notice which is respectively bestowed. Running the eye over the table of contents, we find that separate chapters are devoted to eleven "leading naturalists" of this country. These, of course, must be understood by his general readers, for whom the book is designed, as representing what, in the author's opinion, are the eleven greatest names in the records of British biology. Yet six of these names are Sir Hans Sloane, Gilbert White, Alexander Wilson, William Swainson, Edward Forbes, and Robert Chambers! To take only the first and last of these names, surely when a whole chapter, with a portrait, is devoted to Sir Hans Sloane, it is remarkable that no mention at all should be made of Sir Joseph Banks; or that, when another whole chapter is assigned to Robert Chambers, we should nowhere encounter the name of Robert Brown. It appears to us that when a Professor of Natural History undertakes to popularise his science, his aim should be to place before what this writer calls "unprofessional readers" a true conception of the merit that attaches to solid work in science, as distinguished from the celebrity that belongs to a graceful writer or to an interesting personal character. He should endeavour to raise the popular mind to a just appreciation of *naturalists*: he should not pander to the already accomplished popularity of *authors*. Now, if this has been the aim of Prof. Nicholson—and in his preface he says as much—in our opinion he has shot wide of his mark. But, as before observed, if his object has been to produce a readable assemblage of short biographies, calculated to suit the popular taste, we should say he has every reason to be satisfied with the result.

The Journal of the Royal Agricultural Society of England. Part II., 1886. (John Murray, Albemarle Street.)

THE current number of this *Journal* furnishes an excellent illustration of the wide limits of agricultural science, and the varied knowledge required of its professors. There is perhaps no art or occupation which so directly requires elucidation from so many sciences; hence the varied nature of the bill of fare provided by the *Journal* Committee of the Royal Agricultural Society. In proof of this assertion we may take the contents of the entire volume for 1886, the second part of which lies before us. Pathology is treated of in papers upon foot-and-mouth disease; Pasteur and his work; lung parasites, by the late T. Spencer Cobbold, M.D.; and abortion in cows. Anatomy and physiology are the topics in Prof. Brown's paper upon organs of the animal body, their forms and uses. Chemistry and botany are amply represented in reports by Mr. Carruthers and Dr. J. Augustus Voelcker. Entomology in the form of papers on the recent appearance of the Hessian fly is the theme of Miss E. A. Ormerod. Social science is illustrated by Mr. H. M. Jenkins's report upon farming and agricultural training in reformatory and industrial schools, and engineering in the report of the Judges on the Exhibition of Implements at Norwich.

The more immediately agricultural information is embodied in many interesting papers, among which may be mentioned continued reports upon field and feeding experiments at Woburn; experiments on ensilage conducted at Crawley Mill Farm, Woburn; report on the prize-farm competitions in Norfolk and Suffolk, 1886; the report on the Exhibition of Live-Stock at Norwich; and lessons from the winter of 1885-86.

The number issued during the past month also contains the examination papers on agricultural education set during the present year, and much statistical information useful to agriculturists. With such a large mass of material at hand, it is by no means easy to compress remarks into the limits of a short notice. The names of the authors of the various contributions is a guarantee of their value, and any person who desires to keep pace with scientific agriculture, whether actually engaged in agricultural pursuits or not, will do well to peruse these pages. The most interesting papers, and those containing the newest information on subjects of vital interest to us, are as follows:—(1) An inquiry into several outbreaks of abortion in cows, by C. J. B. Johnson, L.R.C.P., who traces most of the cases to the presence of ergot (*Claviceps purpurea*) in grass and hay. (2) Report on ensilage experiments, in which the results are less favourable to this innovation upon old-fashioned practice than some of the apostles of the movement could wish. Silage is found inferior to homely, honest hay and roots. It is true that silage made from green oats showed a distinct superiority, but the question still remains open whether these promising young oats, sacrificed while in the green stage, might not have developed into still greater value had they been allowed to bloom and fructify and bear their thirty, sixty, or perchance a hundred-fold. Promoters of ensilage have little to congratulate themselves on in this result of strict inquiry and accurate tests brought to bear upon their hobby. No doubt they will be equal to the occasion. The prize-farm competition is, as usual, interesting, but it is a matter of regret that, in such a noted county as Norfolk for farming, the best-known agriculturists, whose farming has been the admiration of their countrymen for generations, should apparently have held aloof from the competition. The first prize was awarded to a suburban farm close to Norwich, and but little can be learnt from management carried on under quite exceptional circumstances. It is also a pity that the able officials of the Royal Agricultural Society do not insist upon a greater uniformity in the reports of their judges in the matter of statistics. For purposes of comparison it would be well if some tabular statement could be made out, as for example as to the amount paid in rent, in labour, feeding-stuffs, and trade expenses; also as to the gross and net produce per acre in each case; the yield of corn in bushels, and of roots in tons; the uses made of straw; the amount of work expected per day from horses and men; the hours of labour; the rate of payment for day and for task work, &c. The reader looks in vain for any such comparisons. Statements regarding them he finds in respect of this or that farm, but any plan by which he may compare or note extremes and means he looks for in vain. Considering the many years in which prizes for the best-managed farms have been given, it is a matter for wonder that it is simply impossible to construct any comparative statement as to points of management in the numerous farms inspected and reported upon. Lastly, we must notice Mr. H. M. Jenkins's report on the cultivation of tobacco in the north-west of Europe, a fairly hopeful paper as to the introduction of this cultivation into England. It would ill become the able secretary of our greatest Society to throw cold water on any suggestion made for the good of agriculture, especially in these sad times; but alas for the frosts of June, July, August, and September, which most of our years carry in their bosoms! Gardeners and farmers know them and dread them. Our summers are not to be relied upon, or we should grow tobacco—ay, and grapes!

JOHN WRIGHTSON

Madagascar: an Historical and Descriptive Account of the Island and its Former Dependencies. Compiled by Samuel Pasfield Oliver, late Captain R.A. Two vols. (London: Macmillan and Co., 1886.)

CAPT. OLIVER has made a useful compilation of information on Madagascar in all its aspects. The compilation consists largely of extracts from previous writers. Capt. Oliver himself visited Madagascar a good many years ago, and has naturally taken much interest in the island and its people ever since. It is evident these two volumes must have cost him much labour, which will no doubt be appreciated by those in search of information on Madagascar in a handy form. After an historical sketch, the first volume is devoted to geography, topography, climatology, geology, and natural history. These, in the second volume, are followed by chapters on natural and agricultural products, ethnology, manufactures, administration, trade and finance, bibliography and cartography, and a very long chapter, with appendixes, on the Franco-Malagasy war. The work, we should say, is exceedingly well supplied with maps and plans, of which there are nineteen altogether.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

An Ice Period in the Altai Mountains

M. B. VON COTTA, who once visited the Altai Mountains, is decidedly of opinion that there are no traces of the Ice period on this range. But at the southern part of the Altai, where there are some large glaciers and many ridges covered with eternal snows, there are undoubted traces of a mighty spreading of ancient glaciers. At least this is the conviction I brought back in 1870 from a rapid examination of nearly the same localities as those which have been recently visited by Mr. Bialoveski.

The deposits of ancient glaciers may be observed, far more to the south, on the ranges of Tarbagatay and Saoor, the southern limits of the basin of the Irtysh. There are not now any glaciers on Tarbagatay, but some sporadic snow-spots. As to the range of Saoor, it attains to the height of 12,500 feet above the level of the sea, and snow always lies there in large masses. But there are no glaciers, properly so called.

Along the northern declivities of these mountains there are at many places large deposits of boulder- or cobble-stones, in great part composed of granite, which forms the crest of both ridges. The boulders are of various rocks and of different sizes, from an inch to some feet in diameter; and they are mingled together in complete confusion, the small boulders being generally well rounded, the large ones more angular, and the intervals being crammed with clay and sand without any traces of layer or assortment. The relation of these deposits to the neighbouring defiles is in most cases incomprehensible. Only at the sources of the River Kenderlik the boulders lie as if the ice which had carried them down had but lately melted. Here, instead of the sections of defiles in the form of the letter **V**, we find, beginning from the elevation of nearly 3000 feet above the level of the sea, a broad defile with transverse section in the form of the letter **U**. The walls (or cheeks, as the Russians call them) of this defile are composed of inclined layers of sandstone and limestone (probably Tertiary deposits), replaced, nearer to the crests, at first by diorite and subsequently by granite. The bottom of the defile is filled up with a close layer of boulder-stones, many of which reach some 10 feet in diameter, the greater number being of gray granite with dark ellipsoidal inclusions. Just the same granite forms the crests of Saoor. To the height of 8500 feet the defile rises steeply enough; but after this limit the inclination becomes more faint. Higher up, the defile grows broader, and at the height of 10,000 feet it is stopped up by two deep valleys crammed with close snow, and surrounded by steep snowy peaks. The full length of the layer of boulders reaches some ten English miles, with a direction from south to north.

The Saoor chain is a post-Tertiary elevation, but the Altai range certainly arose at a most remote time. It must have formed dry land since the Cretaceous formation at least. Here might be found the solution of the question whether there was on the earth an ice period more ancient than that of which we have evidence in the ice-deposits of Europe and North America. Some facts observed by myself seem to me to show that the question must be answered in the affirmative. E. MICHAELIS

Oostkamenogorsk, November 3

How to make Colourless Specimens of Plants to be preserved in Alcohol

MANY plants assume a brown colour when placed in alcohol for preservation. The colouring-matter is partly soluble in the alcohol, partly not, and is the product of the oxidation of colourless substances of the cell-sap. This unpleasant change may be prevented in a very easy manner by using acid alcohol. To 100 parts of common strong alcohol add 2 parts of the ordinary concentrated solution of hydrochloric acid of the shops. Parts of plants brought into this liquid while yet living will become absolutely colourless, or nearly so, after the alcohol has been sufficiently often renewed. Such parts as already had a brown colour before, being brought into the mixture, usually retain this character.

By this method colourless specimens may be made of such plants as *Orobanche* and *Monotropa*, which, when treated in the ordinary manner, always become of a dark-brown tint. There are only some species with coriaceous leaves that cannot be treated with success with the acid alcohol; colourless specimens of these must be made by plunging them into boiling alcohol.

The acidity of the mixture here recommended is nearly 0·2 Aeq. A greater quantity of acid is neither noxious, nor does it improve the effect. A lesser quantity was in many cases found not to be sufficiently efficacious The specimens may remain for months, perhaps for ever, in the acid alcohol without any injury.

If the alcohol, after having been used, is to be decolourised by distillation, the acid should be neutralised by a previously-determined quantity of ammonia or carbonate of soda.

Old specimens, which have become brown in consequence of being treated in the ordinary manner, cannot, as a rule, be decolourised by using the acid alcohol. This, however, may often be done by adding to the alcohol some chlorate of potassa and some sulphuric acid. HUGO DE VRIES

University of Amsterdam, December 1

Virtual Velocities

DE MORGAN in his "Differential and Integral Calculus," p. 501, says:—

"The principle of virtual velocities, like all other fundamental theorems, has had no proof given of it in the admission of which all writers agree. From its universality and simplicity it may be supposed to be rather the expression of some axiomatic truth than the proper consequence of first principles by means of a long course of regular deduction."

Would you kindly allow me to submit to your readers the following attempt to base the principle of virtual velocities and D'Alembert's principle on easily admitted axioms?

(1) The *power* of a force imparted to any molecule is (or is measured by) the product of the force itself, and the effective component in the line of the force, of the velocity of the molecule to which the force is imparted, and is positive or negative accordingly as the force and the effective component of the velocity are in the same or opposite directions.

(2) The power of a system of forces, whether imparted to the

same or different molecules, is the algebraical sum of the powers of the individual forces.

From the parallelogram of motions it follows that—

Prop. I. The power of the resultant of a system of forces imparted to a single molecule is equal to the power of the forces. Whence—

Cor. 1. If the forces imparted to a molecule are in equilibrium, their power for any actual or hypothetical motion of the molecule is zero.

Cor. 2. If the forces imparted to a molecule are not in equilibrium, their power for any motion in the direction of the resultant is positive.

Definition.—A system of molecules is said to be passive for a given motion when for that motion the power of its internal forces is zero.

Prop. II. The power of the external forces of a system for actual or hypothetical motions for which the system is passive is equal to the power of the resultant motions of the several molecules of the system.

For (by Prop. I.) the power of the resultant forces for each (and therefore for all) of the molecules is equal to the power of the external together with that of the internal forces, but the latter, in the case of the entire system, is zero by hypothesis.

Cor. 1. If external forces be imparted to a passive system at rest in a given position such that for any hypothetical motion through that position the power of such forces is zero, the system will remain at rest.

For if motion ensued, the resultant and therefore (Prop. I.) the external forces would have positive power for such motion, which is contrary to hypothesis.

Cor. 2. If external forces be imparted to a passive system at rest, and be in equilibrium, the power of these forces for any hypothetical motion of the system through this position of rest is zero.

For as the whole system is at rest each molecule is at rest, and the resultant forces of the molecules are all of them zero, whence their power and therefore that of the external forces (Prop. I.) is zero.

It will be seen that Prop. II. is (or is equivalent to) *D'Alembert's Principle*, and its two corollaries constitute what is called the *Principle of Virtual Velocities*.

It may be urged that this merely relegates the difficulty to determining for what motions systems are passive. This really, however, presents no difficulty, for it is obvious that a system is passive generally when its internal forces neither tend to produce or destroy kinetic energy in the system; so that (1) rigid systems are passive for all motions consistent with their rigidity; (2) all systems are passive for rigid motion; (3) inelastic and theoretically perfect funicular systems are passive; and (4) inelastic and theoretically perfect fluid systems are passive, &c.

D'Alembert's principle and the principle of virtual velocities ought to form the basis of that part of kinetics which involves the idea of the transmission of force, whether the result is motion or equilibrium. D'Alembert's principle is the most general. The principle of virtual velocities is to it what Maclaurin's theorem is to Taylor's. The form in which it is given in Prop. II. above is more convenient for use than that in which it is generally stated, viz. that the resultant forces reversed balance the impressed forces.

Lagrange's proof of the principle of virtual velocities and its modifications are altogether too artificial and unsatisfactory.

Cape of Good Hope F. GUTHRIE

Recent Gales

THE gales of October 16 and December 8 varied considerably. In the former gale there were constant oscillations, from ·004 to ·010 of an inch, every 30 seconds between 1 a.m. and 2 a.m.; whilst in the December gale there were no oscillations, but a constant fall that was most rapid during squalls. The difference between the dry and wet bulb thermometers in the October gale was only a quarter of a degree, whilst in that of December it exceeded from $2\frac{1}{2}°$ to $3\frac{1}{2}°$ (or a difference of from thirteen to eighteen times as great). During the gale in October, 1·160 inches of rain fell, and in that of December 0·758 of an inch.

The lowest reading (corrected for temperature) of the barometer at 530 feet above the sea was on October 16, 28·019, and on December 8, 27·693 inches (this occurred at 8 p.m.).

The barometer reduced to sea-level was less than 28·5 inches from 11.30 a.m. of the 8th till 8.15 a.m. of the 9th (or nearly 21 hours). The October gale was W.S.W., and the December gale W.

	Hour	Barometer reduced to sea-level	Temp.	Wet bulb	Diff.
Oct. 15,	4.15 p.m.	28·880	49·7	49·5	0·2

	7·0 p.m.	28·987			
10,	10·0 a.m.	29·339	41·6	38·6	3·0

The last gale commenced at 1 a.m. on the 8th (with constant squalls of hail and rain), and was most violent from 4.45 p.m. till 8.30 p.m.

Thunder and lightning occurred from 11 a.m. till 11.30 a.m.; and from 4 p.m. till 4.40 p.m. on the 8th, and from 1.35 a.m. till 2.45 a.m. on the 9th.

Much damage was done to house-roofs. Very few trees were blown down here, for in this exposed situation trees are better prepared to resist gales. About 11 feet of the top of a large specimen of *Picea Webbiana* was destroyed. E. J. LOWE

Shirenewton Hall, Chepstow, December 11

Note on the Manipulation of Glass containing Lead

IN reading Mr. Shenstone's very useful little treatise on glass-blowing (reviewed in NATURE of the 9th inst., p. 123), I have failed to notice any mention of an expedient which I have found very useful for dealing with English flint-glass containing much lead silicate; although I greatly prefer for most purposes the readily fusible "soda-glass" used probably everywhere except in England.[1]

Of course, all ordinary flames, such as those of the Bunsen burner and the blow-pipe, consist, in part, of reducing gases which cause the separation of lead from glass introduced into them. This reduction can be prevented or remedied, as Mr. Shenstone says, by holding the glass a little in front of the visible flame; but there is in this region hardly enough heat to do all that is required in the manipulation of the glass.

If, however, oxygen instead of air is used in a Herapath blow-pipe, the resulting flame has so little reducing power, that lead-glass can be safely held well within it; and this is the flame that I always use in dealing with such glass.

It is true that oxygen is, at present, rather more expensive than air; but most, if not all, laboratories have a supply of the gas, either in a gas-holder or a bag, for the optical lantern and other purposes; and with it the manipulation of lead-glass becomes what shaving is, in certain advertisements, *said* to be—"a luxury." H. G. MADAN

Eton College

P.S.—The oxy-coal-gas blow-pipe is also extremely useful for difficultly-fusible "combustion-tubing." Bulbs of fair size can be blown, and side-junctions, &c., made in this glass, with almost the same facility as in ordinary "soda-glass."

[1] The *best* glass of this kind is that used by Geissler, Alvergniat, and others, for making their marvellous specimens of glass-work; but I doubt if glass of the same excellence, in regard to fusibility and freedom from any tendency to devitrify, is generally procurable.

Fireball of December 4, 1886

THE fireball seen at Stonyhurst College, near Blackburn, on December 4, 9h. 16m., and described in NATURE of December 9, p. 133, was observed here as follows:—

1886, December 4, 9h. 17m., meteor equal ♀. Path from 184° + 52° to 195° + 47°, rather swift. At the point 180° + 50½° it left a short brilliant streak of about ½°, which remained visible to the eye for 1½ minute. The meteor gave a distinct flash in the moonlight, and the streak was projected just where the maximum outburst took place.

I have made a preliminary comparison of the observations recorded at the two places, from which it appears that the fireball, when first seen at Bristol, was some 64 miles vertically over a point of the earth's surface near Farndale, in Yorkshire. Travelling to south west, it evolved an enduring light-streak when 49 miles high, near Thirsk, and disappeared near Otley, at an elevation of 28 miles.

These values are derived chiefly from the Bristol observation, but they are somewhat uncertain, because the meteor was at a great distance from that city, and appeared close upon the sensible horizon. According to the Stonyhurst path, the figures are less, the streak being computed at a height of 42 miles near Thirsk, and the end point of the meteor, near Otley, is indicated at only 19 miles above the earth. The observations are extremely discordant in altitude. The exact place of the streak is given by both observers, and if we adopt a mean height of 45 miles we cannot be far wrong.

The apparent radiant-point derived from the two paths is at 137° + 59°. Before seeing the Stonyhurst observation, I attributed the fireball to a shower near β Ursæ Majoris, at 162° + 58°, from which I saw many swift streak-leaving meteors at the end of November and beginning of December, both in 1885 and 1886. I have a strong suspicion the observed paths of the fireball are slightly in error, both as to direction and length, and that the radiant should be near β Ursæ. In this case the motion would have been from near Guisborough to Harewood at heights of about 68 and 27 miles, but this does not differ materially from the course previously assigned.

In presence of the doubts as to the fireball's exact path in the air, it is most desirable to hear of further observations, and re-investigate it. W. F. DENNING

Bristol, December 11

THE DISPERSION OF PLANTS BY BIRDS

THE part taken by birds in the dispersion of plants is one of great interest in view of the difficulty of accounting for the appearance of certain species in remote islands, no less than in localities nearer to each other, or divided by such barriers as mountain-ranges or deep seas. This subject has, more or less, engaged the attention of botanical travellers from the time when Darwin published his classical "Journal of Researches," nearly fifty years ago, down to the publication of Mr. Hemsley's "Botany of the *Challenger* Expedition," Part I., which was issued as lately as last year. In the careful summary of plants probably distributed by birds, *loc. cit.* pp. 44-49, it is mentioned that seeds may be carried by birds in either of two ways. First, by seeds, especially those provided with barbs and hooks, attaching themselves to the feathers of birds, and, in the case of aquatic or burrowing birds, being embedded in mud and thus carried accidentally outside; or, secondly, by seeds swallowed by frugivorous birds being for a time lodged within, and dejected afterwards in such a state as to be capable of germination. My object now is not to treat generally of this subject, but to place on record two remarkable and striking instances where seeds carried and dispersed by birds have come immediately under my own observation. The examples which I shall here describe will, I believe, show clearly that birds are capable of acting as very effective agents in the dispersal of plants, and that the results are so apparent as to be placed beyond reasonable doubt.

In cases where seeds of a light character are provided with barbs or hooks, they are well adapted for attaching themselves to passing objects, and are most favourably placed for dispersal by means of birds. The particular plant with barbed seeds which I describe under this category has not, I believe, been mentioned before; but it is deserving of notice, as it fully meets all the requirements incidental to this form of dispersal, and, moreover, I have had, for some years, very favourable opportunities of observing its behaviour. This plant is *Uncinia jamaicensis*, Pers. (Cyperaceæ), which grows in damp places in the mountains of Jamaica, at elevations of 5000 to 6000 feet. It is generally found overhanging small pools of stagnant water or on banks of mountain rivulets. Its slender tapering spikes, when ripe, literally bristle with long exserted rachilla, each shaped something like a shepherd's crook (hamate), but with the hooked part so closely fitting and elastic, that, if drawn along the back of the hand, it would grasp and draw out the finest hairs. Now, such places as are affected by this Uncinia are also the frequent resort of numerous birds that come there to drink or bathe, or to seek coolness and shade. In the case of migratory birds, and especially those that cover long distances in their flight, the high lands are generally those first touched. This is doubtless owing to the elevation at which they fly to escape surface-currents or local objects. I have often noticed birds from the north (the United States) on their way south, and again birds from the south returning to the north in early spring, frequenting the high lands of Jamaica, and resting there for a time before continuing their journey. Some such birds have been easily caught by hand, so exhausted were they with their long flight. In two instances I have found small migratory birds so completely entangled in the hooks of the Uncinia (*Gardener's Chronicle*, 1881, p. 780) that they were unable to extricate themselves; and, unless set at liberty at the time, would probably have died in that situation. In these instances the hooks of the Uncinia overstepped their proper function; for, obviously, no benefit would arise to the plant from the death of the birds, but only in the removal of the seed to another place. Larger birds, of course, would not be caught; but on the other hand, if they came within reach of the Uncinia, they could hardly get away without detaching a large number of the fruits and transporting them wherever they went. In the case of the Uncinia, there is present nearly every condition necessary to secure a very complete dispersion of its fruits. The plant, in the first place, is possessed of light portable seeds easily carried about from one locality to another; in the second place, the seeds are provided with highly specialised hooks which effectually grasp anything that comes within their reach; and lastly, the plant affects just those places which are visited by birds, and seldom fails to secure a sure and trusty carrier. It follows, as a matter of course, that *Uncinia jamaicensis* is found plentifully distributed in the track of migratory birds, and is found in similar situations in the mountains on the mainland in Central America, Venezuela, Ecuador, &c.

So much for seeds with barbs and hooks. We now come to the second class of seeds, namely, those which are swallowed by frugivorous birds and dejected in a state suitable for germination. The most striking example I know of the dispersion of such seeds, and of the results which immediately follow, are shown in connection with the pimento industry of Jamaica, which, as shown below, depends entirely for its existence on the offices of frugivorous birds. The pimento of commerce is the dried fruit of the pimento allspice, or Jamaica pepper-tree (*Pimenta vulgaris*). No other country supplies this article (although the tree itself is widely distributed both in the West Indies and on the mainland), and the value of the exports of pimento from Jamaica have reached (in 1880) a total of 100,000*l.* This is probably the largest spice industry in the world, and, to repeat what is mentioned above, it is wholly dependent upon the action of frugivorous birds. In Lunan's "Hortus Jamaicensis," vol. ii. p. 67, published about the end of last century, it is stated that "the usual method in forming a new pimento plantation or 'pimento walk' is nothing more than to appropriate a piece of woodland in the neighbourhood of a plantation already existing; or, in a country where the scattered trees are found in a native state, the woods of which being fallen, the trees are suffered to remain on the ground till they become rotten and perish. In the course of twelve months after the first seasons (rains), abundance of young pimento plants will be found growing vigorously in all parts of the land, being without doubt produced from ripe berries scattered there by the birds, while the fallen trees, &c., afford them both shelter and shade." In a foot-note it is added that "birds eagerly devour the ripe seeds of the pimento, and, muting them, propagate these trees in all parts of the woods. It is thought that the seeds passing through them undergo some fermentation which fits them better for vegetation than those gathered immediately from the tree." The present plan for forming pimento plantations in Jamaica is exactly as described above. In fact, the planters firmly believe that no other plan is likely to produce good pimento walks, although it has been shown by experiments in the Botanical Gardens that by careful treatment plants of pimento can be raised in nurseries in large numbers, exactly as any other economic plants. It remains, however, that all the present pimento plantations in Jamaica have been formed by the action of frugivorous birds, and to this agency alone we are indebted for the commercial supply of a most valuable and wholesome spice.

Kew, December 3 D. MORRIS

SOUNDING A CRATER

THE following is a brief account of my third ascent of Asama Yama, an active volcano about 75 miles north-west from Tokio. My first ascent was made in the spring of 1877. The time we stayed on the summit, which is about 8800 feet above sea-level, was exceedingly short. The crater looked like a bottomless pit, with perpendicular sides. It was audibly roaring, and belching forth enormous volumes of sulphurous vapour, threatening suffocation to any living thing they might envelop. The drifting of these vapours across the snow, with which the upper part of the mountain was covered, had rendered it so bitter that we were unable to use it as a means of quenching our thirst. A quantity of this snow was carried to the bottom of the mountain in a handkerchief, where it was bottled, and carried to Tokio for chemical examination. The examination, however, only yielded *pure* water, from which it was concluded that the liquefaction of the snow had been accomplished by heating over a fire, and whatever it was that had given the snow its peculiarly bitter taste had been evaporated. My next visit to Asama was in the spring of 1886. One of the chief objects of this expedition was to satisfy a curiosity which had arisen with regard to the depth of the crater. Many visitors to the summit reported that at favourable moments, when the wind had blown the steam to one side, they had been able to see downwards to an enormous depth. One set of visitors, who had remarkable opportunities for making observations, were convinced that if the crater was not as deep as the mountain is high above the plain from which it rises (5800 feet), it must at least be from 1500 to 2000 feet in depth. Although I had provided myself with sufficient wire and rope to solve this problem, owing to the inclemency of the weather and the quantity of snow then lying on the mountain the expedition proved a failure. One of our number had to give up the attempt to reach the summit at about 6000 feet above sea-level, while I and my remaining companion only reached it with great difficulty. Our stay was very short. The wind, which was at times so strong that we were often compelled to lie down, rendered it impossible to approach the crater, and after a few minutes' rest we beat a retreat, worn out with fatigue, across the snow-fields, towards our starting-point.

Two months after this, a visitor who ascended the mountain by moonlight reported that the crater was only 200 feet in depth, and that at the bottom there was a glowing surface. A second visitor, Colonel H. S. Palmer, R.E., estimated the depth as being between 500 and 600 feet. This estimate was based on the convergence of the walls of the crater, which he saw to the depth of about 300 feet, and the diameter of the crater, which he estimated by walking round a semi-circumference as about 370 yards. Previous estimates of the diameter had been 200 yards, three-fourths of a mile, and 1000 metres. The Japanese say that the periphery is $3\frac{3}{4}$ miles. These last estimates, as pointed out by Colonel Palmer, are nearly in the ratio of 10, 81, 85, and 150!

These wildly discordant results as to the dimensions of Asama, and the increasing curiosity on this question, led me, in conjunction with Messrs. Dun, Glover, and Stevens, to face the fatigue of ascending Asama for the third time. We left our resting-place, Kutoukake, at the foot of the mountain, at 4.30 a.m. on the morning of October 2, and in company with five coolies we reached the summit at 11 a.m. After a short rest, we commenced our measuring operations, the general arrangements of which were entirely the suggestion of Mr. Dun. When these are explained, they are no more remarkable than the manner in which Columbus caused the egg to stand; but before Mr. Dun made his suggestion, the various schemes which were proposed would, to my mind, have been unpractical and unsatisfactory. One suggestion was to roll a cannon-ball, with a string attached, down the crater; another was to shoot an arrow carrying a string into the hole; a third suggestion was to fly a kite across the crater; &c., &c.

Mr. Dun's method, as carried out, was as follows:—First, a light rope some 500 yards in length was attached to a block of rock lying on a high portion of the rim of the crater. Next, this rope, which I shall call the cross-line, was carried round the edge of the crater for about 150 or 200 yards. Here a heavy brass ring was tied upon it, and through the ring was passed the end of a copper wire coiled on a large reel. This was the sounding-line. Close to the ring, a string, which I shall call the guy-rope, was made fast to the cross-line. This being completed, the cross-line was then carried on round the rim of the crater until it reached an eminence, as near as we could judge, opposite to the point where the other end of it was attached to the block of rock. After this, the same line was jerked clear of pinnacles and boulders lying round the edge of the crater. The cross-line now formed two sides of a triangle, stretching across the crater from where the ring and lowering apparatus were to two points diametrically opposite to each other. By letting out the guy-rope, the cross-rope could be stretched until it formed a diameter to the crater, with the ring in the middle. The getting of these ropes into position was a matter of no little difficulty. First was the fact that clouds of vapours not only prevented us from seeing from station to station, but also from seeing far out into the crater. Secondly, on account of the hissing and bubbling noises in the crater itself, we could only communicate with each other by sound for short distances. And, thirdly, there was the difficulty of clearing the cross-rope from the ragged edges of the crater, which involved considerable risks in climbing. All being ready, word was passed along to haul on the cross-rope; and, as it tightened, the guy-line was let out, together with the sounding-line, running parallel to it, but passing through the ring. Owing to the twisting of the cross-line by tension, and the consequent revolution of the ring, the wire was broken, and the first attempt at sounding failed. This difficulty was overcome by attaching the guy-rope to the ring itself. Very luckily, owing to the sounding-wire having been entangled in the cross-rope by the twisting before it broke, the apparatus it carried was recovered. This apparatus consisted of an iron wire, to which were attached a number of metals of low fusibility, like antimony, zinc, &c., together with pieces of wood, india-rubber, sealing-wax, &c. By the melting, burning, or fusing of some of these, it was hoped to obtain a rough idea of the temperature. Above these came a small net, containing what was christened the "automatic chemical laboratory." This consisted of pieces of blue and red litmus-paper, Brazil-wood paper, and lead paper. With the assistance of my colleague, Dr. E. Divers, I had planned a number of chemical tests; but from previous experience I had learnt the impossibility of carrying out anything but the simplest of experiments when working on the summit of a live volcano.

At the second sounding, at a distance of about 100 feet from the edge, bottom (side?) was reached at 441 feet. The wire of metals, &c., came up without change, farther than the softening and bending of the sealing-wax. The automatic laboratory had a strong smell of the action of acid vapours. The blue litmus was turned red, and the lead paper was well darkened. Assuming the lead paper to have been blackened by sulphuretted hydrogen, then, as pointed out to me by Dr. Divers, the absence of this gas at the surface, and the presence of sulphurous acid, might be due to the decomposition of sulphuretted hydrogen by oxidation or by sulphurous acid in the presence of steam. The presence of sulphuretted hydrogen would indicate a relatively low temperature.

At the third sounding, the line, which was a copper wire, gave way at a depth of about 200 feet, carrying with it a mercurial weight thermometer and other apparatus which I had reserved for what I hoped to be the best sounding.

The fourth and last sounding was made, as measured on the guy-rope, at a distance of about 300 feet from the edge. In this case, the line, which was strong twine, after striking bottom when nearly 800 feet of it had run out suddenly became slack. On hauling up, 755 feet were recovered. The end of this line was thoroughly carbonised, and several feet were charred. Assuming that the guy-rope was paid out at an angle of 45°, we may conclude that the depth at this particular place was *at least* 700 feet. It is probable that the greatest depth is about 750 feet

A final experiment was to attach a stone to the end of the cross-rope, and then throw it into the crater, with the hope of hauling at least a portion of it up the almost perpendicular face on the other side. Unfortunately the line caught, and, in the endeavour to loosen it, it was broken.

Before we left the summit, we were very fortunate in obtaining views of one side of the bottom of the crater. This we did by cautiously crawling out upon an overhanging rock, and then, while lying on our stomachs, putting our heads over the edge. The perpendicular side opposite to us appeared to consist of thick horizontally-stratified bands of rock of a white colour. The bottom of the pit itself was white, and covered with boulders and debris. Small jets of steam were hissing from many places in the sides of the pit, while on our left, where we had been sounding, large volumes of choking vapours were surging up in angry clouds.

After this we descended the mountain, reaching our hotel at 8 p.m., after 15 hours' absence.

This concludes the narrative of a holiday excursion, partly undertaken with the object of making a few scientific observations. The results which were obtained are undoubtedly very few, while the labour which was expended and the risks which were incurred were very great. All that we did was to solve a problem chiefly of local interest, to learn a little about the nature of the gases which are given off by one of the most active volcanoes in this country, and to enjoy the spectacle of a phenomenon which it is the lot of very few to witness When a stranger gazes for the first time down upon the burnt and rugged sides of an apparently bottomless pit, which, while belching out enormous clouds of steam, roars and moans, he certainly receives an impression never to be forgotten.

The recorded eruptions of Asama took place in the years 687, 1124 or 1126, 1527, 1532, 1596, 1645, 1648, 1649, 1652, 1657, 1659, 1661, 1704, 1708, 1711, 1719, 1721, 1723, 1729, 1733, 1783, and 1869. This last eruption was feeble, but the eruption of 1783 was one of the most frightful on record. Rocks, from 40 to 80 feet in some of their dimensions, were hurtled through the air in all directions. Towns and villages were buried. One stone is said to have measured 264 by 120 feet. It fell in a river, and looked like an island. Records of this eruption are still to be seen, in the form of enormous blocks of stone scattered over the Oiwake plain, and in a lava-stream 63 kilometres in length. JOHN MILNE

Tokio, October 10

THE MATHEMATICAL TRIPOS[1]

II.

VERY important regulations came into effect in 1848. The examination, as thus constituted, underwent no further alteration till 1873, and the first three days remain practically unchanged at the present time. The duration of the examination was extended from six to eight days, the first three days being assigned to the elementary and the last five to the higher parts of mathematics. After the first three days there was an interval of eight days (soon afterwards increased to ten), and at the end of this interval the Moderators and Examiners issued a list of those who had so acquitted themselves as to deserve mathematical honours. Only those whose names were contained in this list were admitted to the five days, and after the conclusion of the examination the Moderators and Examiners, taking into account the whole eight days, brought out the list arranged in order of merit. No provision was made for any further examination corresponding to the examination of the Brackets, which, though forming part of the previous scheme, had been discontinued for some time. A very important part of the scheme was the limitation, by a schedule, of the subjects of examination in the first three days, and of the manner in which the questions were to be answered; the methods of analytical geometry and differential calculus being excluded. In all the subjects contained in this schedule, examples and questions arising directly out of the propositions were to be introduced into the papers, in addition to the propositions themselves. Taking the whole eight days, the examination lasted $44\frac{1}{2}$ hours, 12 hours of which were devoted to problems.

In the same year as these regulations came into force, the Board of Mathematical Studies (consisting of the mathematical Professors and the Moderators and Examiners for the current and two preceding years) was constituted by the Senate. Although the new regulations had so strictly limited the subjects, and parts of the subjects, which could be set in the first three days, they had imposed no limitation whatever upon those which could be set in the last five days, the subjects of examination appearing in the schedule simply as pure mathematics and natural philosophy. Accordingly, the first matter to which the newly-constituted Board turned its attention was that of restricting the subjects on which questions should be set in the last five days of the examination.

It becomes necessary, therefore, at this point, to refer

[1] Address delivered before the London Mathematical Society by the President, Mr. J. W. L. Glaisher, M.A., F.R.S., on vacating the chair, November 11, 1886. Continued from p. 106.

briefly to the range of subjects which were included in the examination. Of the nature of the questions proposed prior to 1828, the first year in which all the papers were printed, very little can be known except what can be gathered from the problem papers and the specimens of the other papers that have been preserved;[1] but there can be no doubt that their character was determined by the ordinary Cambridge treatises then in use, which, it is well known, were far behind the corresponding treatises published on the Continent. Woodhouse's "Principles of Analytical Calculation" (1803), and "Plane and Spherical Trigonometry" (1809) are the earliest indications of the introduction of the analytical element into the mathematics of the University; a more decided impulse in this direction was given by the translation of Lacroix's "Differential and Integral Calculus" by Herschel, Peacock, and Babbage (1817), followed by Peacock's "Examples on the Differential and Integral Calculus," and Herschel's "Examples on the Calculus of Finite Differences" (1820).

The reform in the mathematical studies of the University which was effected by Herschel, Peacock, and Babbage, is well known. It is to them that we mainly owe the revival of mathematics in this country, and the restoration of intercourse with the rest of Europe after three-quarters of a century of isolation. Peacock was Moderator in 1817, and he ventured to introduce the symbol of differentiation into the examination, his colleague, however, retaining the old fluxional notation. The old system made its appearance once more in 1818, but in 1819 Peacock was Moderator again, with a colleague who shared his views, and the change was fully accomplished.

The introduction of the notation and language of the differential calculus into the Senate House examination forms an important landmark in the history of Cambridge mathematics. From that time onward the University began to make up slowly but surely the ground she had lost; step by step the analytical processes and methods superseded the older geometrical modes of treatment; and each year saw a substantial increase in the range of subjects included in the course of study.

Only second in importance to the revolution effected by the substitution of the differential for the fluxional calculus was the rise of analytical geometry in the first thirty years of the century; and, considering the amount of attention that this subject has received at Cambridge in the last fifty years, and the accessions that have been made in this country to the analytical theory of curves and surfaces, a peculiar interest attaches to the introduction into the University of the algebraic treatment of geometry and the early stages of its development. The first edition of Wood's "Algebra," which appeared in 1795, contained, as Part IV., a chapter of thirty pages "On the Application of Algebra to Geometry," in which are given the equations of the straight line, ellipse, cissoid, conchoid, and other curves, the construction of equations, &c. This chapter remained unchanged in the ninth edition (1830), and seems to have formed the only introduction to analytical geometry existing in the University until 1826, when Hamilton[2] published his "Principles of Analytical Geometry, designed for the use of Students in the University." This was not the first English treatise on analytical geometry, as Lardner's "Algebraic Geometry" was published, three years earlier, in 1823; but it was the first Cambridge book, and the first which included solid geometry. The problem papers from 1800 to 1820 show that at the beginning of the century analytical geometry was always represented to some extent, though scarcely as an independent subject, most of the questions relating to areas, loci, &c., in which but little more than the mode of representation by means of ordinates and abscissæ was involved. Hymers published his "Analytical Geometry of Three Dimensions" in 1830, and his "Conic Sections" in 1837. The latter at once superseded Hamilton's treatise, and remained the standard work on the subject for many years.

In applied mathematics the character of the questions proposed was largely influenced by the publication of Whewell's "Mechanics" (1819), Whewell's "Dynamics" (1823), Coddington's "Optics" (1823), Woodhouse's "Plane Astronomy" (1821-23), and Airy's "Tracts" (1826). A second edition of this last work, which appeared in 1831, contained a tract on the "Undulatory Theory of Light," a subject which was freely represented in the examination for many years. Not only were the questions modified, in character and range, by the publication of new mathematical treatises in the University, but they were also affected to a certain extent by some of the professorial lectures. At this time, too, the Smith's Prize examination exerted a beneficial effect upon the Senate House examination, certain classes of questions which were originally introduced into the former having shortly afterwards been admitted into the latter. Between 1830 and 1840, questions in definite integrals, Laplace's coefficients, electricity, magnetism, and heat were also introduced. There were no regulations of any kind, and the responsibility of introducing innovations and alterations rested solely with the Moderators and Examiners. The uncertainty as to the subjects that the examination would embrace, and the want of any due notice of any extension of them, were found to be serious inconveniences to the higher class of students, although, as has been already stated, the introduction of a new subject had been generally preceded by the publication of a work by a Cambridge mathematician, in which it was treated in a manner adapted to the examination.

The Board of Mathematical Studies was created by the Senate on October 31, 1848, and in May of the following year they issued a report to the Senate in which, after giving a short review of the past and existing state of mathematical studies in the University, they recommended that, considering the great number of subjects occupying the attention of the candidates and the doubt existing as to the range of subjects from which questions might be proposed, the mathematical theories of electricity, magnetism, and heat should not be admitted as subjects of examination. In the following year they issued a second report in which they recommended the omission of elliptic integrals, Laplace's coefficients, capillary attraction, the figure of the earth considered as heterogeneous, &c., besides certain limitations of the questions in lunar and planetary theory, &c. In making these recommendations the Board expressed their opinion that they were only giving definite form to what had become the practice in the examination, and were only putting before the candidates such results as they might themselves have deduced by the study of the Senate House papers of the last few years. The Board also recommended that the papers containing book-work and riders should be shortened.

From 1823 onwards, the examination was conducted in each year by four examiners—the two Moderators and the two Examiners, the Moderators of one year becoming as a matter of course the Examiners of the next. Thus of the four examiners in each year two had taken part in the examination of the previous year. The continuity of the examination was well kept up by this arrangement; but perhaps it had the effect of causing its traditions to be rather too punctiliously observed, the papers of each year being, as regards the subjects included, exact counterparts of the corresponding papers of the previous year. The resolutions of the Board in 1849-50 were not binding on the successive Moderators and Examiners up to 1872, but each year they seem to

[1] The problem papers were printed from 1772; but only those of the present century are accessible in the Cambridge University Calendars and other publications.

[2] Late Dean of Salisbury: born April 3, 1794; died February 7, 1880.

have felt themselves bound to follow the precedent of their predecessors, so that no new subjects were introduced. One would suppose from an examination of the papers set that those of the last five days must have been framed in accordance with a schedule as precise and detailed as that which governed the first three.

In 1865 the Board recommended that after 1866 Laplace's coefficients and the figure of the earth considered as heterogeneous should be included in the examination, but this appears to be the only extension of the range of subjects recommended by the Board during the time that the regulations of 1848 remained in force.

The period that followed the constitution of the Mathematical Board was one of activity in the whole University. The first examinations of the Moral Sciences Tripos and of the Natural Sciences Tripos were held in 1851. In 1850 a Royal Commission was issued to inquire into the University and Colleges, and in 1852 their Report was presented to Parliament. In consequence of this Report, a Bill was introduced into Parliament, which received the Royal assent in 1856; and, under its powers new statutes were framed, both for the University and the Colleges. Amid all these changes the Mathematical Board, though not very active, was not idle. The subjects which chiefly occupied its attention were the alteration of the date of the first three days from January to the previous June (as by recent changes the poll-men were examined in June, and so received their degrees seven months before the mathematical honour men), and the introduction of the *vivâ voce* element into the examination. Neither of these innovations, though frequently discussed and finally recommended by the Board, was received with much favour in the University. With regard to the latter, the opinion seems now to have become general that an admixture of the *vivâ voce* element, however valuable it may be in the lecture-room, is useless, or even worse, in testing the proficiency of candidates with the view to arranging them in strict order of merit. The change of time from January to June was at length effected, as will be seen, by the regulations which came into operation in 1882.

In 1866 the attention of the Board was directed to the exclusion of certain important branches of mathematics from the studies of the University, owing to the fact that they were not represented in the Tripos examination. The rewards attending a high place in the Tripos were so great that the reading of most of the best men was directed almost wholly to this end; it was therefore practically impossible to introduce new mathematical subjects into the University without assigning to them some place in the Tripos. Now, although the recommendations of 1849-50 had curtailed the range of subjects, the course had nevertheless extended itself in some directions—where the name of the subject permitted of such extension—and especially in analytical geometry and higher algebra. The fact of this extension taking place in certain subjects, while others were wholly omitted, alone sufficed to show the need of some revision of the limitations imposed upon the subjects that might be set. The Board, after careful consideration, came to the conclusion that the time had come when it was desirable to allow the candidates a certain option with respect to the higher branches of mathematics, and that this could be effected by increasing the number of subjects and arranging them in several divisions over which the marks were distributed in a known proportion. Each candidate would be at liberty to devote himself to such of the divisions as he thought most advantageous, there being nothing to prevent his taking up all the divisions, if it were possible for him to do so. In a Report dated May 8, 1867, the Board gave expression to these views, and recommended a scheme for the five days, according to which the subjects of examination were arranged in five divisions, with an approximately determinate number of marks assigned to each division. The subjects included in the five divisions were thirty-five in number, and included elliptic integrals, elastic solids, heat, electricity, and magnetism. On June 3, 1867, a syndicate was appointed by the Senate to consider the proposals of the Board; and the regulations recommended by this syndicate were approved by the Senate on June 2, 1868, and came into operation in January 1873.

In this new scheme of examination the three days were left unchanged, and the schedule of subjects for the five days, and their arrangement in divisions as proposed by the Board, were adopted with very slight modifications, the marks awarded to the five divisions being to those awarded to the three days in the proportion of 2, 1, 1, 1, $\frac{2}{3}$ to 1 respectively.[1]

The new regulations also made two other changes of importance: they added an extra day to the examination and increased the number of the examiners from four to five. The extra day was the day immediately following the three days, and it was devoted to easy questions upon the subjects in the five days' schedule. Although the papers set on this fourth day were put before all the candidates, they were taken into account along with the five-day papers, and not with the three-day papers; so that this day had no effect upon the alphabetical list of those who deserved mathematical honours; which, as before, was dependent upon the three days' marks only.

The Additional Examiner was appointed on the nomination of the Mathematical Board, and held office for one year only; and, to render his duties as little irksome as possible, he was not required to take part in the first three days—the most laborious part of the examination as far as the looking over the papers is concerned, on account of the quantity of work sent in. It was thought that in introducing the new subjects of electricity and magnetism into the examination, certain non-resident Cambridge mathematicians whose names were closely connected with great recent advances in these subjects might be willing to give the University the benefit of their assistance, and that the influence of eminent non-resident mathematicians upon the examination, and therefore also upon the course of studies in the University, would be of the greatest value. These hopes were abundantly justified.

The general working of the new system soon disclosed the fact that the desired effect of inducing the best candidates to make a selection from the higher subjects, and concentrate their reading, had not been attained. It was found that, unless the questions were made extremely difficult, more marks could be obtained by reading superficially all the subjects in the five divisions than by attaining real proficiency in a few of the higher ones; and the best men of the year were tempted, not to say compelled, to extend their reading as widely as possible over the book-work of the whole range of subjects. Thus, with respect to the main object which the framers of the scheme had in view, it was a complete failure.

Accordingly, on May 17, 1877, a syndicate was appointed by the Senate to consider the higher mathematical studies and examinations of the University. This syndicate consisted of eighteen members representing nearly all phases of mathematical research and study in Cambridge; they met every week during the whole academical year, and the thorough examination and discussion that the subject received, both on the syndicate and in the University at large, brought out in the strongest light how great were the intrinsic difficulties connected with the retention of the order of merit, and how wide was the diversity of opinion—so much so, that at one time it seemed almost hopeless to attempt to devise a scheme

[1] The regulation assigning the proportion of marks to be awarded to the different divisions was one which was found in practice very difficult to carry out, even approximately.

that should receive a fair amount of general support. Even when the subjects were restricted, as they had been in the twenty-five years from 1848-72, it was sufficiently difficult to include in one list all the various classes of candidates—those who may be described as professed mathematicians, who intended to devote themselves to mathematics after their degree as investigators or teachers; those who adopted mathematics as their subject of study on account of its unrivalled mental training, and subordinated their whole reading to the single object of obtaining the highest place their abilities would enable them to reach; and those who, without any hope of obtaining a good place in the list, desired, nevertheless, to graduate in the Tripos, on account of the high position held by mathematics among the branches of a liberal education. But, when the range of subjects was extended, there was the further dilemma: if there was to be a single order of merit, all the questions must be submitted to all the candidates; but, if a candidate was to be at liberty to attempt all the questions, it appeared that, under any scheme that could be devised, the best candidates would find it more to their advantage to read the elementary portions of all the higher subjects than the higher portions of a few. If the questions were to be alternative, how could the order of merit be retained? How was it possible to compare one student's elliptic functions with another's elastic solids? was a question often asked.

It was keenly felt in the University that subjects like heat, electricity, and magnetism could not with propriety be omitted from the course systematically studied by candidates for mathematical honours. On the other hand, it was universally admitted that, by the extension of the range of subjects, the severe strain of the competition had been intensified to an injurious extent; and not only had the addition of the new subjects aggravated the evils arising from excessive competition, but they had even caused a deterioration in the quality of the work of many of the students, who were led, in the hope of gaining higher places, to attempt matter really beyond their grasp. The opinion was expressed on the syndicate that the only escape from the dilemma was by abandoning the order of merit. The majority, however, preferred to attempt some other remedy without interfering with the final form of the Tripos list, which had been of such immense service to the University in the past, and was connected with so many valued associations. They therefore proposed, as the only method by which the pressure on the mathematical candidates could be relieved, to omit a varying portion of the higher subjects of examination in each year.

The Report of the syndicate was presented to the Senate on March 29, 1878. They recommended that the nine days of the examinations should be divided into three groups of three days each, called Parts I., II., and III. Part I. was to be the same as the first three days in the schemes that came into operation in 1848 and 1873. Part II. was to be conducted according to a schedule of subjects considerably more restricted than the unwritten schedule that ruled the five days from 1848 to 1872. It included the more elementary portions of most of the ordinary subjects, such as differential equations, hydrostatics, rigid dynamics, optics, spherical astronomy, &c, but excluded calculus of variations, thermodynamics, physical optics, &c. It was proposed to move forward the time of examination in these first two parts, from January to the previous June, *i.e.* two years and nine months from the time of coming into residence of the students. After the examination in Parts I. and II. a list of the candidates was to be published, arranged in three classes as before, the senior and junior optimes being placed in order of merit, and the wranglers in alphabetical order. Only the wranglers were to be admitted to Part III., which was to take place at the old time in the following January. A final list was then to be issued in which the wranglers were to be placed in order of merit, the marks obtained by them in all three parts being added together. The most important part of the scheme was the schedule of subjects for Part III. It contained all the subjects which were included in the schedule of the five days of the then existing examination (for the syndicate had decided that they would neither propose the addition of any new subjects nor the omission of any that had been already included), divided into three groups, A, B, C. It was recommended that questions from the subjects in group A should be set every year, and that questions from groups B and C should be set in alternate years. It was thus proposed to establish, as it were, a "rotation of subjects." This scheme was voted upon by the Senate on May 13, 1878, when all its essential features were rejected. The division of the examination into three parts, of which the first two should take place in June and the third in the following January, was agreed to, as also was the limitation of Part III. to wranglers; but the carrying over the marks of the wranglers from June to January and the proposed rotation of subjects were rejected.

It is evident that the acceptance of the scheme, even by those who assented to its principle, depended largely upon the manner in which the subjects were divided into the three groups A, B, C. Whether a satisfactory division of the subjects was possible is very doubtful; but it is certain that the grouping of the subjects proposed by the syndicate was extremely unsatisfactory.

This scheme, though it never came into operation, will be memorable in the history of the Tripos as the final attempt made to retain the order of merit in its old form. With its rejection there passed away all hope of expressing the results of the whole examination by means of a single order of merit. The scheme also deserves notice for its own sake, if only on account of the influential mathematicians who supported it.

The syndicate then proceeded to build a new scheme upon the ruins of the old. They considered that the result of the voting on the nineteen graces in which the previous scheme had been submitted to the Senate showed that it was the opinion of the University that the examination in Part III. should be independent of the preceding parts, and that no scheme would be acceptable in which it was not provided that all the subjects should be included in the examinations of each year. They accordingly presented a Report to the Senate in October 1878, in which they proposed that in June, immediately after the examination in Parts I. and II., the complete list of wranglers, senior optimes, and junior optimes should be issued arranged in order of merit, that Part III. should be a separate examination, to which wranglers only should be admissible, and that after the examination in Part III. a list should be issued in which the candidates were arranged in three classes, the names in each class being arranged in alphabetical order.

The schedule of subjects consisted of all the existing subjects divided into four groups, A, B, C, D. Group A contained the pure mathematics; Group B, the astronomical subjects; Group C, hydrodynamics, sound, physical optics, elastic solids, &c.; and Group D, heat, electricity, and magnetism. In order to encourage the candidates to specialise their reading, one of the regulations authorised the Moderators and Examiners to place in the first division a candidate who showed eminent proficiency in any one group; so that it was not absolutely essential for a student, in order to be placed in the first division, to extend his reading beyond the subjects of a single group.

This scheme was approved by the Senate on November 21, 1878, and it came into operation in 1882, the first examination in Part III. taking place in 1883.

Parts I. and II. taken together differed in no essential respects from the Tripos as it had existed from 1848. The five days of the scheme of 1848 were reduced to three, and the range of subjects was more limited; otherwise the examination was exactly the same as in the period 1848–72. But Part III. was a complete novelty, and a great deal of curiosity was felt as to how the first Moderators and Examiners would interpret the regulations. Would the new examination resemble, as regards the character of the questions set, the last three days of the old five days, or was the examination to be one of a distinctly higher order? The result showed that the latter anticipation was the correct one. No longer hampered by the order of merit, the examiners felt themselves free to set difficult and elaborate questions, such as were only appropriate to specialists in the particular subjects; and a new departure was made.

As soon as the new system came into full operation, it was found that it needed amendment in various respects; and this is not to be wondered at, considering that it had been constructed in order to fit in with the few regulations that had escaped the general massacre of May 1878, and that almost every part of it was the result of a compromise. It was found that the interval between June and January —less than seven months, and including a long vacation in which very few lectures were given—was too short for an adequate preparation for Part III. It is true that most of the work for Part III. could be done—and indeed was done—before the examination in Parts I. and II.; but the competition in these two parts remained as keen as ever, and, as the examination became imminent, the candidates were tempted to neglect the higher work, and give their whole attention to the more elementary subjects, upon which the list in order of merit depended. As a consequence there was a diminution in the numbers of students attending the higher mathematical lectures in the University. With respect to the actual conduct of the examination, it was found that the strain upon the Moderators and Examiners was very serious, and general regret was expressed that under the new scheme no provision had been made for the annual appointment of an Additional Examiner, as in the previous scheme which had been in operation from 1873 to 1882. Under the new system the candidates devoted themselves to special branches of the higher mathematics, and there was even greater difficulty in adequately representing all the subjects of examination. Accordingly, on June 12, 1884, the Senate confirmed a Report of the Mathematical Board recommending that the examination in Part III. should take place in June, exactly a year after that in Parts I. and II., and that the Moderators and Examiners, with the Chairman of the Mathematical Board, should nominate an Additional Examiner, the first nomination being made in the Easter term, 1885, and having reference to the examination in January 1886. It was considered that the Moderators and Examiners were themselves the best judges of the branches of mathematics in which they most desired assistance, and were therefore the most suitable body to nominate the Additional Examiner.

The last time that the whole examination took place in January was in 1882. This year (1886) the examination in Part III. has taken place in January for the last time, so that the historic connection between the Tripos and the month of January has now finally ended. Henceforth the examination in all three parts will take place in the middle of the year.

(*To be continued.*)

EARTHQUAKE AT SEA

WE have received the following communication from Mr. R. H. Scott, F.R.S., Secretary, Meteorological Office:—

British Consulate, St. John's, Porto Rico, November 4, 1886

SIR,—I have the honour to inform you that Mr. J. Simmons, master of the British brigantine *Wilhelmina*, of Lunenburg, now loading in this port, has reported to me that, on October 20 last, at 4.30 p.m., while in latitude 19° 21′ N., and longitude 64° 22′ W., he felt a shock of earthquake which caused the ship to tremble. The shock lasted one minute, and was accompanied by a loud rumbling noise like distant thunder. Capt. Simmons states further that, were it not that he believed the depth of water at the spot to be no less than two thousand fathoms, he could have imagined that his vessel was running upon the rocks, so great was the vibration and so loud the noise. I have thought it my duty to report this occurrence officially, as it seems not improbable that some volcanic disturbance is in operation in the locality herein referred to.

I have the honour to be, Sir, your most obedient humble servant,

REGINALD H. HERTSLET, H.M. Consul

The Assistant Secretary, Marine Department, Board of Trade

NOTES

WE regret to hear of the death at Calcutta of Father Scortechini from dysentery. He has succumbed to his extraordinary exertions in the botanical exploration of Perak, where he had made very large and valuable collections. These he intended to make the basis of a flora of this native State in collaboration with Dr. King, the Superintendent of the Royal Botanic Garden, Calcutta. His collections will, as far as possible, be made use of by Sir Joseph Hooker in the portions of the flora of British India now in progress at Kew.

ONE of the severest storms of recent years swept over the country in the middle of last week, being indeed a storm seldom paralleled for its wide-spread destructiveness. The damage to property and the loss of life have been exceptionally great, and each morning newspaper has been adding to the long tale of losses and disasters. Another peculiarity of the storm is that it was heralded with only the slightest premonitions of its approach. It was at Valencia only that the observations of the previous evening indicated a storm, and these even seemed to foreshadow no more than a subsidiary cyclone. But on Wednesday morning last week the centre of the storm had already advanced on the north-west of Ireland, where at Belmullet, at 8 a.m., the barometer had fallen, at 32° and sea-level, to 27·580 inches. In the course of the day the cyclone moved eastward at the rather slow rate of 20 miles an hour, and by 6 p.m. its centre was near Barrow-in-Furness, where the barometer is stated to have fallen to 27·410 inches. The centre passed somewhat to the south of Edinburgh, about half-past seven, pressure being then 27·650 inches, and the wind easterly. The greatest interest is attached to the observations that may have been made in the north of England and the south of Scotland during the evening of Wednesday week, from which the path of the cyclone may be traced; and particularly, if the low reading at Barrow-in-Furness be confirmed, what lower readings of the barometer were made to the eastward. But in any case it is plain that in this part of Great Britain, on the evening of Wednesday week, pressure fell nearly as low as it did on January 26, 1884, at Ochtertyre, Perthshire, where it fell to 27·333 inches; and it is remarkable that these two low barometers, hitherto the lowest observed by man anywhere on the land surfaces of the globe after being reduced to sea-level, have occurred in the British Islands, and within three years of each other. It is noteworthy that the lowest pressure on Ben Nevis was 23·451 inches at 2h. 31m. p.m., and that at the height of the storm, at 6 p.m., the wind was south-east, and blowing at the rate of fully 120 miles an hour—thus indicating that the storm was not only wide-spread, but that it also, as regards direction and force of wind, extended to a greater altitude than the Ben Nevis Observatory.

MR. T. H. COX, of the firm of Cox Brothers, manufacturers, Camperdown Linenworks, Lochee, has given a donation of 12,000*l.* for the endowment and equipment of a Chair of Anatomy in connection with the Medical School it is proposed to establish in University College, Dundee.

WE are glad to notice that in the new French Ministry M. Berthelot, the eminent chemist, takes the portfolio of Education.

AN electrical metronome has been established at the Paris Opera House, which enables the *chef d'orchestre* to conduct choruses at any distance from his chair. The working is very satisfactory, and the effect really admirable.

THE late Prof. Morris at the time of his death had made considerable progress with a third edition of his "Catalogue of British Fossils." Some of his friends, reluctant that so valuable a work should be lost to science, have arranged to revise and complete the manuscript, and the necessary expenses of preparing it for the press have been guaranteed by his nearest surviving relative, who rightly holds that this will be the best monument to his memory. The editor-in-chief is Dr. H. Woodward, of the British Museum, and he is assisted by a number of eminent specialists, among whom are Drs. Hinde and Traquair, Profs. Duncan, Rupert Jones, Lapworth, Nicholson, and H. G. Seeley, Messrs. Carruthers, Etheridge, Hudleston, and Lydekker. The Syndics of the Cambridge University Press have now undertaken the publication of the work, which it is hoped may appear in the course of the coming year.

THE annual distribution of prizes and certificates to the successful students at the City and Guilds of London Institute was held on Monday night, when the Lord Chancellor gave an address in which he contrasted the restrictions which hampered industrial progress in the past with the complete freedom and publicity of the present day.

A VIOLENT shock of earthquake occurred at Smyrna and also at Chios on the morning of December 11. Frequent oscillations have been felt at Smyrna during the past fortnight, causing fissures in the walls and fronts of many houses in the town. A shock was felt on the 8th in Missouri City and in Missouri State, and a shock is also reported from Columbia, South Carolina. On the night of November 1, at 12.15 p.m., a sharp shock was felt at Nordheinsund, on the west coast of Norway. Houses and windows shook, whilst a man walking in the road felt the earth slowly rock under him. The shock, which was accompanied by a heavy rumbling noise, was from northwest to south-east.

A CORRESPONDENT in South Africa writes:—"*Rogeria longiflora*, the Martynia-like plant, has capsules which pierce the lips of the gnu or 'wildebeest,' and are rubbed to pieces in their efforts to get rid of them. Truly, what with *Uncaria*, costing the life of a springbok for every capsule trodden out, and *Rogeria* festering in the poor 'wildebeest's' mouth, the beneficent 'Nature' of the teleologist is in Africa a remarkably cruel divinity."

IN an interesting recent paper on Siberia as a colony, Prof. Petrie points out that there are two classes of colonists there—those attracted by the immense wealth of the country in furred animals and minerals, and an industrious people from the Russian peasant class engaged in agriculture. The number of wild animals taken in the boundless forests of Siberia shows a great reduction from year to year. The fisheries are capable of great development, and multitudes of fish are thrown away because the art of salting and preserving is not understood. In Ural, the southern steppes, Altai, and other places, there is immense mineral wealth in silver, gold, iron, lead, copper, anthracite, graphite, &c. The steppes (quite different from the Central Asiatic and Kirghisian) are well suited for cattle-breeding; they have excellent grass and numerous birch woods, and also many lakes, large and small. In Western Siberia, about 32 per cent. of the whole land is arable. With her four rivers of the first rank, three of them flowing north and the other east, Siberia is well off for intercommunication by water and for transport of commerce to neighbouring countries. Notwithstanding three hundred years of occupation, the Russians in Siberia only amount to 4,800,000, and there are nearly as many natives. The Russian colonist in Siberia diverges from the Sclav type, as the Yankee does from the Englishman. At present, farming and cattle-breeding in Siberia are carried on in an irrational way, commerce is in absolute dependence on European Russia, and the roads are dreadfully bad, so that, *e.g.*, people commonly make circuits rather than use the post route from Tomsk to Irkutsk. There is, however, a party of intelligent Siberians bent on gaining the liberties and advantages of the mother country, stopping the deportation of criminals, and promoting education, &c. Many thousand roubles have been contributed by Siberian merchants to found the Tomsk University and other institutions.

MR. J. B. MEDLAND, of 12, Borough, has sent us a specimen of his new portable cabinet for microscope-slides. The cabinet has sixteen trays to hold nine objects each, contained in a well-made polished pine case. When closed, it is the same height and width, and only two inches and a half longer than the ordinary case holding only half the number. Each glass slip is held at its ends by the projecting side flap of the tray, which is held down by the succeeding tray, and so on, the lid holding the whole firmly down. When open, the lid and front fall back, forming a stand or table to place the trays upon, keeping them together and less liable to get displaced or upset, as when placed among other apparatus or upon the desk or work-table. The advantages of the cabinet will be obvious to microscopists.

A WORK by Mr. J. Allen Brown will appear early in January, published by Messrs. Macmillan and Co., entitled "Palæolithic Man in North-West Middlesex; the Evidence of his Existence, and the Physical Conditions under which he lived in Ealing and its Neighbourhood, illustrated by the Condition and Culture presented by certain existing Savage Races."

THE Council of the Essex Field Club has determined in future to issue the *Transactions* and *Proceedings* of the Club combined in the form of a monthly periodical, entitled *The Essex Naturalist; being the Journal of the Essex Field Club.* The journal will contain papers read before the Club, reports of past and announcements of future meetings, and, as space allows, notes and communications upon any matters of interest connected with the natural history, botany, geology, and prehistoric archæology of Essex. We believe that this is a new departure in the policy of local societies, at least in the south of England, but the plan has been adopted by the Essex Club from a rapidly growing conviction that, if local societies are to flourish and do useful work, it is necessary to devise some means of "keeping touch" with their members, and encouraging intercommunication among them. The first number of the *Essex Naturalist* will appear in January next, and will be conducted by Mr. W. Cole, who has edited the publications of the Club since its establishment seven years ago.

THE Japanese Government has despatched an official of the Ministry of Commerce to Norway, in order to study the cod-fisheries, the preparation of oil, &c., in that country, the object being to develop these industries in Northern Japan, where large numbers of cod appear at certain seasons.

SOME important geological work has just been carried out at Landsort, near Stockholm. Close to the coast, pipes have been driven through the rock to the sea, by which sea-water will be carried up into a specially constructed kiosk for examination and registration, the object being to measure the elevation of the shore in course of time. It is intended to establish similar stations at various places on the coast.

BETWEEN 8 and 9 o'clock on November 3 a remarkable phenomenon was observed at Hamar, in Norway. At the time there was perfect darkness, when, suddenly, a bright white cloud appeared in the sky, drifting in a north-easterly direction, and from time to time emitting brilliant rays of light in various directions. The cloud retained throughout its original form, and disappeared at last in the darkness.

FISH-HATCHING operations have now commenced at the establishment of the National Fish Culture Association. The new hatchery that has lately been constructed is completed, and a batch of ova has already been laid down for incubation. These were taken from *Salmo fontinalis* located in the ponds of the establishment. A large number of rainbow trout (*S. iridens*), of California, hatched out two years ago by the Association, from ova sent by the American Government, will be ready to spawn at the end of the year, which is six weeks earlier than in their native waters. This shows to what extent fish alter their natures and habits according to the climatic and other conditions of their locations. The *S. iridens* is a late spawner in its native country, which is accounted for by the hardness of the water and the low temperature that prevails. It is hoped to secure a large quantity of ova from these fish. The American Government have announced their intention of forwarding consignments of ova from Transatlantic Salmonidæ. A feature is to be made this year of hatching ova for Fishery Boards and other public bodies, who will collect ova from their respective waters and forward them to the Association for incubation. When hatched, the fry will be turned into the parts from whence they came.

ACCORDING to the *Colonies and India*, a discovery of much geological interest has just been made at Cockatoo Island, Sydney. A large fossil shell of the genus Planorbis was found in the excavation for a new Government dock at Cockatoo Island, and was forwarded to Mr. Wilkinson, the Government Geologist of New South Wales. This being the first fossil shell found in the Hawkesbury formation, he took the opportunity of examining the rocks, but only obtained some fossil plants. As, however, the rocks looked promising for fossil remains, he sent the collector, Mr. Cullen, to make a further search, which was rewarded by the discovery of a most interesting fossil, which Prof. W. J. Stephen has identified as *Mastodon aurus*, of which a similar fossil specimen from Stuttgart is in the collection of the Sydney University. This being the first discovery in Australia of Labyrinthodon, is of much scientific importance, as proving the Triassic age of the Hawkesbury sandstone formation.

THE first number is to hand of the *Proceedings* of the Camera Club, the President of which is Capt. Abney. It is nicely printed, and will no doubt prove useful to members and to photographers generally.

THE additions to the Zoological Society's Gardens during the past week include a Sclater's Curassow (*Crax sclateri* ♀) from South America, a Razor-billed Curassow (*Mitua tuberosa*), a Lesser Razor-billed Curassow (*Mitua tomentosa*) from Guiana, presented by Rear-Admiral Fairfax, R.N., F.Z.S.; a Spanish Terrapin (*Clemmys leprosa*) from Spain, presented by Miss Eden; eighteen Brown Newts (*Spelerpes fuscus*), South European, presented by Prof. H. H. Giglioli, C.M.Z.S.; two European Phyllodactyles (*Phyllodactylus europæus*) from Cannes, presented by Mr. J. C. Warburg; two Peruvian Thicknees (*Œdicnemus superciliaris*) from Peru, an Allied Saltator (*Saltator assimilis*) from Brazil, an Australian Sheldrake (*Tadorna tadornoides*) from Australia, received in exchange; a Common Zebra (*Equus zebra* ♂) from South Africa, two Shore Larks (*Octocorys alpestris*), British, purchased.

OUR ASTRONOMICAL COLUMN

PUBLICATIONS OF THE WASHBURN OBSERVATORY, VOL. IV.—In the month of March 1884, Prof. Holden offered to Prof. Auwers to undertake the observation at Madison of the 303 fundamental stars required for the southern zones of the Astronomische Gesellschaft. In view, however, of the smallness of the staff of the Observatory, Prof. Holden would only pledge himself to secure four complete observations of each star; but, with his assistants, Mr. Comstock worked with so much zeal and energy that on his appointment to the Lick Observatory in the autumn of 1885, the stars from 0h. to 6h. of R.A., and from 12h. to 24h. had all been completely observed six times, the number Prof. Auwers had desired, in each element. Mr. Updegraff and Miss Lamb, who had latterly been Prof. Holden's assistants, succeeded in bringing the entire work to completion by the close of 1885, no fewer than 6444 observations of stars, irrespective of observations of the nadir point, having been secured in the course of its carrying out. The observations were always kept in a forward state of reduction, and thus the present volume contains the results of the entire work. Prof. Holden was not, however, able to give the observations so full a discussion as he had intended, and as they themselves seemed to merit by their accuracy. The probable error of a single R.A. of stars of the 303 list, observed in 1884, he found to be $\pm$ 0·037s. for himself, $\pm$ 0·031s. for Mr. Comstock; and for a single declination, for himself $\pm$ 0″·400, for Mr. Comstock $\pm$ 0″·436.

The results of these observations, which were made with the Repsold meridian-circle of 4·8 aperture, an instrument of essentially perfect optical and mechanical quality, naturally occupy the greater part of the present volume. It also contains some other matters of interest, amongst which may be noted a series of observations with wire screens before the object-glass of the meridian telescope, for the purpose of ascertaining the effect of magnitude on the recorded time of transit, and the determination of the longitude of a station near the western boundary of Dakota. It has been Prof. Holden's effort also to make the collection of star catalogues in the library of the Observatory as complete as possible, and for that purpose he has bought most of the principal catalogues attainable, and marked in them, so far as possible, all the errata which were known to him. A list of the sources from whence these corrections have been derived is here given, and will doubtless be of considerable use to other astronomers.

THE SECOND ARMAGH CATALOGUE OF 3300 STARS.—Dr. Dreyer, on his appointment to the direction of the Armagh Observatory after the death of Dr. Robinson, found a great mass of unpublished meridian observations which had been accumulating since 1859, the date of the publication of the first Armagh Catalogue. On the completion of that great work, Dr. Robinson had formed the plan of re-observing a number of stars occurring in Baily's Catalogue from Lalande's "Histoire Celeste," and the observations were commenced in 1859, but the work was interrupted at the end of the following year, the Primate, Lord John George Beresford, having generously provided a new telescope of 7 inches aperture for the mural circle, instead of the old one of 3¾ inches aperture. The idea of Dr. Robinson, of converting the mural circle into a transit instrument by the addition of a second pier, was not, however, carried out. The observations were recommenced in April 1863, the Rev. W. H. Rambaut being the observer from August 1864 to July 1868, and the Rev. C. Faris from November 1868 to the beginning of 1882. Dr. Dreyer himself observed during 1883, with the end of which year the observations close. Considering that the majority of the stars had, in the course of late years, been observed in the zones of the Astronomische Gesellschafte, and that nearly all might be expected to be included in the forthcoming great Paris Catalogue, Dr. Dreyer thought it important to publish the Armagh results as speedily as possible, and the Government Grant Committee of the Royal Society having promised to meet the cost of publication, the present Catalogue was prepared. It contains the results of the whole of the meridian work carried on at the Observatory since 1859;

containing thus, with the first Armagh Catalogue, a complete record of all the meridian work accomplished at the Observatory since 1827; for the results published in the *Transactions* of the Royal Dublin Society in 1872, and forming a catalogue of 1000 stars, have been incorporated in the present work, as there were numerous unpublished observations of many of the stars there given.

The R.A.'s of the present Catalogue depend on the standard stars of the *Nautical Almanac*, four or five of which were observed on each night, whilst the N.P.D.'s depend upon observations of the nadir point, the adopted being 54° 21′ 12″·70. Dr. Robinson's investigation of the division-errors of the circle (*Mem. R.A.S.*, vol. ix.), and also his refraction-tables (Armagh Catalogue, pp. 834–35) have been used. The details of the construction of the refraction-tables, which may be considered as identical with Bessel's, are given in the *Transactions* of the Royal Irish Academy, vol. xix. The places of the stars are reduced to the epoch 1875·0, with Struve's constant, but proper motions were never taken into account. The Catalogue, which is very clearly printed, and forms a very compact and neat-looking volume, contains for each star its number in Lalande, its magnitude, generally from the DM., its mean R.A. and N.P.D. for 1875·0, together with the annual precession, the number of observations, the epoch and references to other modern star catalogues, this last column being very complete. The secular variation has been omitted. The introduction also contains a comparison between the present Catalogue and Prof. Grant's Glasgow Catalogue of 6415 stars, not only because it was deduced from observations made nearly at the same time as the Armagh observations and depended in R.A. on the *Nautical Almanac* stars, but also because it had already been rigorously compared by Prof. Auwers with his "Fundamental Catalogue." From the comparison of 539 which the two catalogues have in common, it would appear that the Armagh and Glasgow Catalogues, though perfectly independent of each other, are in fair agreement, so far as N.P.D.'s are concerned. But the R.A.'s appear less satisfactory, as considerable discordances are evident. These Dr. Dreyer thinks may be readily accounted for, partly by the one-sided character of the instrument, partly by the conjecture that perhaps the azimuth found by observing the meridian mark may not be strictly applicable on the opposite (south) side of the zenith. The comparison with Auwer's "Fundamental System" gives a similar result, the N.P.D.'s agreeing much better than the R.A.'s. The probable error of a single observation found from 400 observations of 80 stars between 30° and 100° N.P.D. was R.A. ± 0·081s., N.P.D. ± 0″·85.

Great credit is due to Mr. Faris for his perseverance in continuing and reducing the observations during thirteen years, and to the present Director for his energy in completing and publishing the entire results, which will not fail to be a useful addition to our star catalogues.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 *DECEMBER* 19–25

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on December 19

Sun rises, 8h. 4m.; souths, 11h. 57m. 21·5s.; sets, 15h. 50m.; decl. on meridian, 23° 26′ S.: Sidereal Time at Sunset, 21h. 43m.

Moon (one day after Last Quarter) rises, 0h. 42m.; souths, 6h. 52m.; sets, 12h. 51m.; decl. on meridian, 1° 8′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	6 3	10 26	14 49	18 54 S.
Venus	8 25	12 14	16 3	23 58 S.
Mars	10 0	14 2	18 4	22 4 S.
Jupiter	2 53	8 3	13 13	10 31 S.
Saturn	17 35*	1 39	9 43	21 38 N.

* Indicates that the rising is that of the preceding evening.

Meteor-Showers

Ursa Major supplies a couple of radiants at this season—one near ι, R.A. 131°, Decl. 48° N., the other near α, R.A. 157°, Decl. 64° N. December 19 and 21 are fireball dates.

SANITARY PROGRESS DURING THE REIGN OF THE QUEEN[1]

IN opening the meetings of the One Hundred and Thirty-third Session, it appeared to me that, as we are entering upon the jubilee year of the Queen's reign, it might be interesting to take stock, as it were, of the progress which has been made by the nation in some one of the branches of usefulness to which the proceedings of this Society have contributed; and it occurred to me that the most fitting subject to select would be that of the progress which has been made in sanitation during Her Majesty's reign.

The year 1838 was the first complete year of registration.

The first report of the Registrar-General brought forward the sanitary condition of different parts of the country, and of different classes of the population. Disease was as prevalent amongst the labouring population in rural villages as it was in the most crowded and filthy districts in towns, and, on the motion of the Bishop of London, the House of Lords, in August 1839, presented an address to the Queen, begging her to direct an inquiry into this prevalence of disease. From this period may be said to date that great social and sanitary movement which has tended so largely to ameliorate the moral as well as the physical condition of the people of this island, and which forms one of the most prominent features of the Queen's reign.

The Poor-Law Commissioners were directed to report upon the condition of the labouring classes; and the direct evidence of much preventable disease, which the records of disease and death furnished from all parts of the country, formed the basis on which the Commission founded their recommendations. In towns, the people were crowded in courts and alleys; they swarmed in cellars which were neither ventilated nor drained. In 1837, it was calculated that one-tenth of the population of Manchester, and one-seventh of the population of Liverpool, lived in cellars.

The dead were buried in overcrowded churches, chapels, and churchyards in the middle of towns. The rural districts were no better.

In the towns this condition of things arose from the great increase of population which had been taking place for some years previously, coincident with the rapid expansion of our trade and manufactures, coupled with the absence of legislative provisions to meet the new exigencies which had arisen, and with which the older laws, in consequence of that increase, were unable to cope.

But there were other active causes. For instance, the Commissioners state that parochial administration operated mischievously in degrading the habitations of the labouring classes,

[1] Abstract of Address by Capt. Douglas Galton, C.B., F.R.S., at the opening of the Session of the Society of Arts.

and in checking tendencies to improvement. The depression of the tenement depressed the habits and condition of the inhabitants.

In speaking of the insanitary condition of houses, we must not forget the effect of the window tax. This tax had been established for 150 years. Air and sunshine are the first requirements of healthy dwellings, and the window tax induced every builder to shut out the sun and exclude the air, so that poor men were unable to afford the luxury of adequate windows for their dwelling-rooms, or of any windows for their closets. Darkness and dirt go hand in hand, and in the class of houses above the cottages, darkness and want of ventilation were much fostered by the window tax. This tax was not abolished till 1851.

At the commencement of the Queen's reign, drainage over the whole country was provided for by various Commissions of Sewers. Their duty was limited to causing "to be made, corrected, or repaired, amended, put down or reformed, as the case shall require, walls, ditches, banks, gutters, sewers, gates, cullises, bridges, streams, and other defences by the coasts of the sea and marsh ground."

The Highway Acts provided for road cleansing and road structure; and there was a law for cleansing of ditches, which forbade throwing offal and foul refuse into the ditches which might lead to the pollution of streams.

The most important, perhaps, because the most cheap and accessible, authority for enforcing the execution of the law for the protection of the subject against nuisances, and for punishing particular violations of it, was vested in the Courts Leet. The juries, commonly called "annoyance juries," impanelled to serve on courts leet in towns, perambulated their districts to judge of nuisances upon the view; but the Commissioners reported that, with all this legal strength, there was scarcely one town in England found in a low sanitary condition, or scarcely one village marked as the abode of fever, that did not present an example of standing violations of the law, and of the infliction of public and common as well as of private injuries, the tenements over-crowded, streets replete with injurious nuisances, the air rendered noisome by these and by the smoke from factory chimneys, and the streams of pure water polluted.

As regards smoke, most of the then modern private Acts contained penalties on gas companies, prohibiting their washings to contaminate streams, or using for steam-engines furnaces which did not consume their own smoke. The general statute, 1 and 2 Geo. IV., c. 41, empowered the Court to award costs to the prosecutor of those who used such furnaces; but the duty of informing was not placed on public officers, and private individuals were unwilling to become informers.

The provision of pure water, and the disposal of the water after it had been fouled, had scarcely been thought about. No doubt, in London, and in some large towns, water was provided by public companies or by the corporation; but in almost every country town the water supply was defective.

The report on the sanitary condition of the labouring classes states that it was difficult to conceive the great extent to which the labouring classes are subjected to privations, not only of water for the purpose of ablution, house-cleansing, and sewerage, but of wholesome water for drinking and culinary purposes. Whilst, however, the water supply was insufficient even in London, on the other hand the necessity for providing means for getting rid of the fouled water was generally ignored.

It is stated, in the report of 1842, that the courts inhabited by the poorer classes in towns are generally not flagged; they are paved with a sort of pebbles; they are always wet and dirty. The people, having no convenience in their houses for getting rid of waste water, throw it down at the doors; that scarcely one house for the working classes will be found in which there is such a thing as a sink for getting rid of the water. It mentions, in a typical case, that, where in one locality a large sewer had recently been made, the landlords are not compelled, and do not go to the expense of making any communication from the courts to the sewer; the courts are as wet and dirty, and in as bad a condition as they were before the sewer was constructed; and it is added that this miserable accommodation in the wretched courts pays a better percentage than any other description of property; it pays as much as 20 per cent. in many instances.

With regard to fæcal matter, the general practice had been for each house to have its cesspit, which was emptied at intervals by night men; but in the poor districts the soil was allowed by the occupiers to accumulate for years to avoid the expense of emptying. Within the preceding twenty years water-closets had been introduced into the better class of houses. The refuse from these was generally allowed to flow into the cesspits; but, to avoid the expense of frequent emptying, an overflow was made, where practicable, into sewers or adjacent ditches; in other cases the refuse was turned directly into the sewers, and created a dangerous deposit.

The danger had begun to be noticed long before; for in 1834 one medical witness stated to a Committee of the House of Commons that of all cases of severe typhus that he had seen, eight-tenths were either in houses of which the drains from the sewers were untrapped, or which, being trapped, were situated opposite gully holes; and the report of the Poor-Law Commissioners remarks that this recent mode of cleansing adopted in wealthy and newly-built districts by the use of water-closets, which discharge all refuse *at once* from the house through the drain into the sewers, whilst it saves delay, prevents accumulation, and also saves the expense of hand labour; yet has the objection that if much extended it may pollute the water of the river into which the sewers are discharged. They, however, recommend that this danger should be incurred, as a lesser evil than the retention of the refuse in houses; adding that—

"It is possible to remove the refuse in such a mode as to avoid the pollution of the river, and at the same time avoid the culpable waste of this most important manure."

The conditions under which the drains had been constructed were entirely different from those which became necessary with the increase of population. The sewers had been constructed for land drainage, and only with reference to the wants of the immediate locality, so as just to drain it to the nearest outlet, without any reference to any general plan of sewerage. The sewers were generally flat at the bottom, of stone or brick; the joints were not specially water-tight, so that much of the liquid passed into the surrounding soil, and the floor of the sewers was covered with deposit, which had to be removed at much expense by hand, and in many cases the size and form of the sewers were adapted to enable the workmen to enter for cleansing purposes. When new lines of houses were built, new sewers were required for which outlets into the old sewers did not afford sufficient fall, and they then became choked with deposit. The cleansing of streets was not performed with uniformity or rapidity; and the condition of many of the back streets and courts was deplorable. They were not properly paved, and had no conveniences.

The Poor-Law Commissioners recommended, in the report already mentioned, that the expensive and slow process of the removal of the surface refuse of the streets by cartage might be dispensed with, and the whole at once carried away by the mode which is proved, in the case of the refuse of houses, to be the most rapid, cheap, and convenient, namely, by sweeping it at once into the sewers, and discharging it by water. This recommendation was largely adopted.

In order to convey some idea to your minds of the difficulties which would necessarily be caused by turning the street sweepings, which consisted largely of mud from macadamised roads directly into the sewers, I may mention that at the present time in London every effort is made to stop the road material from passing into the sewers by sweeping the streets, and by placing catchpits at the gullies and cleansing them frequently, and that in the metropolis the quantity of dirt from roads and gullies, and of deposits from sewers, removed annually, amounts to nearly 1,000,000 tons, and the annual quantity in those days cannot have fallen far short of 350,000 tons. The combined effect of turning the street sweepings and the water-closet refuse into sewers, with uneven falls and flat bottoms, naturally added to the deposit, and intensified the evils in such a manner as finally to force on improvements in the construction of the sewers.

The difficulties as to drainage and the removal of refuse were principally entailed by the absence of any legal machinery to enable the inhabitants of a locality to combine for sanitary purposes, and to share the expenditure necessary for improvements.

Another important insanitary condition was caused by the fact that the vagrant population of the kingdom resorted to common lodging-houses, which were under no sort of supervision, and which were *foci* for the propagation of epidemic disease, as well as of moral depravity.

The general conclusions at which the Poor-Law Commissioners arrived in their report on the condition of the working classes were that disease originating in, or propagated by means of, decomposing refuse and other filth, and damp, close, and overcrowded dwellings, prevailed generally among the working classes in all parts of the kingdom ; and that whilst these diseases could be abated by improved sanitary conditions, they were not removed by high wages and abundant food if sanitary conditions were absent. They also pointed out that owing to the defective water-supply cleanly habits were impossible.

In illustration of the loss caused to the nation by these preventable diseases, they mentioned that out of 43,000 widows and 112,000 destitute orphans relieved from the poor-rates, the greater number had lost their husbands or fathers from preventable diseases ; and that the youthful population of either sex brought up in crowded, unwholesome dwellings, and under the adverse circumstances described, were deficient in physical strength and moral conduct, and grew up improvident, reckless, and intemperate, caring for nothing but sensual gratification. They pointed out that the expenses of local public works were unequally and unfairly assessed, oppressively and uneconomically collected by separate collections, and wastefully expended by unskilled and irresponsible officers, and that the existing law for the protection of the public health, and the constitutional machinery for its execution, such as the Courts Leet, have fallen into desuetude.

The Commission then went on to state the conditions required for improving the sanitary condition of the labouring classes.

This report was thus one of the early fruits of the system of vital statistics which commenced at the accession of the Queen, under the able supervision of our late eminent member, Dr. Farr. The report itself was drawn up by another eminent member of this Society, Mr. Edwin Chadwick, C.B. It is a remarkable tribute to the foresight of Mr. Chadwick that, during the last half-century, almost all the sanitary principles laid down in the report have been recognised by the Legislature as necessary to the welfare of the community, and have become matters of ordinary practice. The conclusions of the Poor-Law Commissioners, and the general interest awakened in the subject, led to various sanitary investigations, both by Royal Commissions and Committees of the Houses of Parliament.

When the Registration Act came into operation, an epidemic of small-pox was advancing over this island. It attained its maximum in the spring of 1838, and destroyed 30,819 persons. Dr. Farr mentions that vaccination protected a part of the population, but that there is reason to believe that inoculation led to the extension of the epidemic by diffusing the infection artificially. In 1840 and 1841, the first Vaccination Acts were passed. These prohibited inoculation, and empowered the Guardians to provide means for vaccination, and to charge the expense on the rates ; and enacted that vaccination was not to be considered parochial relief, thus recognising the fact that the community should bear the cost of measures which are found necessary to secure the public health. It was not, however, till 1853 that vaccination was made compulsory.

The reports of the various Commissions and Committees of Parliament which inquired into the condition of the people showed the great importance of cleanliness of person and clothing to health, and the difficulties which the poor suffered in respect of it ; and in 1844, private associations, not only in London, but in Manchester, Liverpool, and other large towns, were formed to encourage cleanliness amongst the working classes by establishing public baths and wash-houses, and lending out pails, brushes, and whitewash to the poor to cleanse their dwellings ; and in 1846, the Bishop of London brought in a general Act empowering local authorities to establish public baths and wash-houses, the expense of which was to be defrayed out of the rates.

As regards general sanitary legislation, it is probable that the recommendations in the Poor-Law Commissioners' report and in the reports of these several Royal Commissions and Committees of the Houses of Parliament, would have remained long in abeyance had it not happened that the nation was threatened with an epidemic of cholera.

In 1832-33, the cholera had visited our shores and snatched 16,437 victims. It again appeared in London on September 22, 1848, and in Edinburgh in the beginning of October, 1848. So long as the insanitary conditions remain, epidemics invariably haunt the same localities, and the first appearance of the cholera in Bermondsey in 1848 was close to the same ditch in which the earliest fatal cases occurred in 1832. The first case of cholera that occurred in the town of Leith took place in the same house and within a few feet of the very spot from whence the previous epidemic of 1832 commenced its course. On its reappearance in 1848 in the town of Pollockshaws, it snatched its first victim from the same room and the very bed in which it broke out in 1832. It did not, however, attain its full intensity until 1849, and it ceased on December 22, 1849. Its progress fully corroborated the report of the Poor-Law Commissioners. It attacked those towns and houses which offered to it the best inducements to visit them, in their filth, decaying refuse, crowded and dirty population, bad water, damp polluted subsoil, or any other of those conditions which lead to bad health in a population, and which, when cholera is absent, afford an evidence of their existence by the prevalence of scarlet fever, small-pox, typhoid and other fevers, measles, whooping-cough, &c. The total number of victims was 53,293.

The near approach of the cholera led Parliament, in 1848, to the conclusion that—

"Further and more effectual provision ought to be made for improving the sanitary condition of towns and populous places in England and Wales, and it is expedient that the supply of water to such towns and places, and the sewerage, drainage, cleansing, and paving thereof, should, as far as practicable, be placed under one and the same local management and control, subject to general supervision."

An Act was passed creating a General Board of Health. The main feature of this Act was, that when the Registrar-General's returns showed that the number of deaths on an average of the preceding seven years exceeded 23 per 1000, the General Board of Health were empowered to send an inspector to make a public inquiry as to the sewerage, drainage, water supply, burial-grounds, number and sanitary condition of inhabitants, and local Sanitary Acts in force ; also as to natural drainage areas, the existing local boundaries, and whether others might be advantageously adopted. The General Board were empowered to issue provisional orders, creating a system of local administration by means of Local Boards of Health, consisting partly of municipal authorities and partly of elected members. These Local Boards were empowered to appoint necessary officers, including medical officers of health, surveyors, and inspectors of nuisances. The public sewers were vested in the Local Board, and they were to maintain, cleanse, and regulate the use of sewers. All houses rebuilt were required to be provided with drains approved by the surveyor ; and, before any new house was commenced, the levels of the cellars or lowest floors, and the position and character of the drains or cesspools, were to be approved by the surveyor. The occupation of cellars as dwellings was prohibited. Water-closets, or privies, and ash-pits were to be provided to all houses and workshops. The Local Board was also required to manage, repair, and clean the streets, and to provide for removal of refuse. They were to abate nuisances, regulate slaughter-houses, register and make by-laws to regulate common lodging-houses. The local authorities were empowered to provide public recreation-grounds, and to provide a water supply, except where a water company would supply on reasonable terms. They were also to provide mortuaries ; to obtain power to close burial-grounds which they considered to be unhealthy, and to open new ones.

The Local Boards were empowered to make by-laws and impose penalties, subject to confirmation by the Secretary of State, and to levy rates, to mortgage the rates, and to borrow from the Public Works Loan Commission. The Act also provided for sewers, wells, pumps, &c., to be made where desired by the inhabitants in parishes containing less than 2000 persons. The metropolis was exempted from the operation of this Act.

The General Board of Health came into existence in 1848, just before the outbreak of cholera in this country, and it took measures at once to check the disease, and proclaimed the principles upon which the preventive and other measures for meeting the epidemic ought to be conducted. Amongst these measures, probably the one which had the greatest effect in promoting subsequently a general feeling of the necessity for sanitary improvements, and which awoke in the nation the needs of moral improvement, was that requiring house-to-house visitation, and the cleansing of the houses and streets, and obtaining an adequate water supply.

This epidemic also brought into notice the necessity of appointing efficient medical officers to supervise the sanitary condition of the different towns and districts.

Further Acts for regulating the public health were passed in 1858, 1861, and subsequent years ; and all their provisions were embodied in a General Act in 1875, from the operation of which the metropolis was exempted. Subsidiary to these may be mentioned the Acts regulating rural water supply, the Artisans' and Labourers' Dwellings Acts, or what have been more recently termed the housing of the working classes, and also Acts for checking the adulteration of food, as well as other Acts relating to the diseases of animals. This general legislation has been largely supplemented by by-laws issued by local authorities, with the sanction of the Local Government Board, and by means of Local Acts obtained by various towns.

The Act of 1848 initiated the system which subsequent legislation has supplemented, under which many towns and rural districts have borrowed money for and have executed public sanitary works during the last forty years. The importance of this measure may be gauged by the fact that the money borrowed since that time for sanitary works, and not yet repaid, amounts to over 130,000,000*l.*, in addition to very large sums spent out of current rates; and in addition to an enormous private expenditure, which is beyond the reach of calculation, for the reconstruction of house drains. This legislation and expenditure have caused a complete revolution in that branch of engineering science connected with public health, viz. drainage and water supply, and has gradually established it on a scientific basis.

Modern sewerage may be said to date from the introduction of oval forms in sewers, by Mr. Roe and Mr. Phillips,[1] under the Commissioners of Sewers, in 1845; the construction of impervious clay pipes for smaller drains; the recognition of the necessity that sewers and drains should be water-tight and self-cleansing; and that junctions should be carefully made. Ventilation of the sewers followed a severe outbreak of typhoid fever, consequent upon the construction of a new unventilated sewer at Croydon. In 1849-50, Sir Robert Rawlinson introduced the system of constructing sewers and drains in right lines from point to point, with lamp-holes or man-holes at every change of direction or of gradient; this is now the recognised method of construction among all English-speaking races. The reconstruction of the sewers led to a reform in house drainage, of which the leading characteristics are imperviousness of material, free aëration, and facility of inspection at all points.

The disposal of water-carried sewage began by leading to the widespread pollution of our streams and rivers, and the serious injury of the sea beach in many of our seaside health resorts. The problem was complicated by the doctrine that as the pollution was caused by a vast amount of fertilising matter, large profits might be made out of its removal. But those who made this assertion generally overlooked the fact that the conveyance of the refuse would have to be paid for just like any other work. The subject has been repeatedly discussed in this hall, but it is far too extensive for me to enter into here.

Let us now turn from the community generally to the metropolis, which was excluded from the operation of the Sanitary Acts of 1848 and 1875. The population of London was 960,000 in 1801. At the Queen's accession it had more than doubled, and amounted to about 1,900,000. At the present time it is very nearly 4,000,000. The metropolis has, from its situation, all the attributes of a healthy city. It lies in a valley through the centre of which the Thames sweeps from west to east, and the winds rushing over its water afford a continuous supply of fresh air to the middle of the City. But the advantages of this situation had been largely frustrated by the unopposed efforts of the landowners to accumulate the greatest possible number of houses on the least possible space, by which the free circulation of air was impeded in some districts, and the families of artisans were crowded in small, low, close rooms, without space for the safe retention of refuse; and there was no adequate machinery for its rapid removal.

London is now, undoubtedly, the finest capital in the world. It was far from being so at the beginning of the Queen's reign. Among other things, there were deplorable deficiencies in the sewerage. The drainage found its way through badly-formed, leaky drains into the old water-courses, and thence to the river; the sewage was floated up and down by the tide in the heart of London, until it was deposited on the shore at low water in fetid banks, which covered the foreshore from Blackfriars to Battersea.

One of the early effects on the metropolis of the report of the Poor-Law Commission, was a Metropolitan Building Act for improvement of drainage, and for securing a sufficient width of streets and alleys, and due ventilation of buildings, and to regulate the construction of buildings, authorising the vestries to appoint district surveyors.

[1] Mr. Phillips is at present employed in superintending the reconstruction of the drainage of the Houses of Parliament.

In 1846, a new Commission of Sewers was formed, and charged with the duty of revising the metropolitan drainage. The Commissioners applied for an Ordnance survey of the metropolis, which was commenced in 1847.

The water supply of London was furnished by water companies, who trenched upon each other's districts. Its volume may be assumed, at the Queen's accession, to have been about 36,000,000 gallons per twenty-four hours. It was estimated by Mr. Wicksteed, in 1845, at 45,000,000 gallons. Some was derived from the tidal part of the Thames, and was more or less filtered; but, from its doubtful purity, pumps in surface-wells, often adjacent to churchyards, were frequently preferred for drinking-water. In many of the courts and smaller streets water was obtained only from a small stand-pipe, where the water was turned on for an hour or less daily, when the inhabitants stood around waiting with whatever vessels they might have at hand for their turn to procure a portion of a miserably scanty supply, which was then stored for use in probably the only room occupied by a whole family. Amongst the poorer classes, almost the only receptacles that existed were wooden butts, frequently in a state of decay; and, as they were for the most part without covers, the water was placed under favourable circumstances for the reception of dirt and refuse and for the development of animal and vegetable growths.

After the cholera epidemic, the question of the purity and quantity of the water supply attracted notice; and in 1852, Parliament passed an Act forbidding the supply of water from the tidal part of the Thames or its tributaries, and requiring all river water to be filtered and to be kept covered after filtration; also requiring a constant service when demanded by four-fifths of the houses in a district. In 1858, the average daily supply had risen to 75,000,000 gallons. In 1871, another general Act was passed, to make further provisions for securing to the metropolis a constant supply of pure water; this Act defined the sources of supply of the several companies, and required, amongst other matters, efficient filtration, and the application of tests of purity.

The amount of water delivered into London by the water companies for September last was 178,196,597 gallons in twenty-four hours, of which about 90,000,000 gallons came from the Thames above Teddington Lock; its purity is ascertained by continual analysis; and it may now be said that the water supplied to London rivals that of any other city in purity.

It was not till 1852 that the Secretary of State was authorised to prohibit burials within the metropolis.

A new era in metropolitan sanitation was inaugurated in 1855. In that year the Metropolitan Board of Works was created. In this body was vested the main drainage of the metropolis, but the charge of the subsidiary parish sewers was left to the vestries, who were also charged with the care of the streets and roads, the Metropolitan Roads Commission being abolished, and all duties of lighting, control of removal of refuse, &c., were placed on the vestries.

Thus the formation of this new Board was somewhat of a retrograde movement, because the concentration of functions, which had been commenced under the Metropolitan Roads Commission and Metropolitan Sewers Commission, instead of being strengthened in the new Board, was abandoned, and something approaching chaos was introduced. This Board has, however, by degrees had remitted to it the care of London improvements, and certain other general municipal functions, as well as power to levy general rates. The City retained its individuality, excepting as to the main sewers, and effected improvements and opened out thoroughfares in the part under its jurisdiction. The improvements in the other parts of London are mainly due to the action of the Metropolitan Board of Works. Great alterations have taken place in our thoroughfares. Many of those large tracts of London which were occupied by dwellings of the most wretched description, are now traversed by wide thoroughfares, and covered by artisans' dwellings erected by private enterprise. But there is no diminution of the rate at which the vast aggregation of population in London still continues to progress; and, unfortunately, many of the wretched crowded dwellings still remain, where those born in close rooms, brought up in narrow streets, and early made familiar with vice, are deteriorated in physique, and grow poorer from inability to work.

The reconstruction of the drains, the removal of the sewage from the midst of the population, the opening out of thoroughfares so as to admit ventilation into crowded districts, have all tended to improve the sanitary condition of London.

I have some interesting tables, prepared for me by the kindness of Mr. A. J. Mundy, of the Registrar-General's Office, which show the remarkable sanitary results of these various efforts. The death-rate of London in the five years 1838-42 was 25·57 per 1000. In the five years 1880-84 it was 21·01 per 1000; and the deaths from zymotic diseases, which in the decade 1841-50 had averaged annually 5·29 per 1000, were reduced in the years 1880-84 to 3·4 per 1000. If, however, we assume that there had been no change in sanitary conditions, and therefore that the death-rate had gone on increasing according to Dr. Farr's formula of increase due to density of population when the sanitary conditions remain unchanged, the death-rate of 1880-84 would have averaged 26·62 per 1000; that is, a saving of 5·61 per 1000 has been effected by sanitary measures.

If upon this basis we compare the saving in life which has resulted from sanitary improvements at different periods since 1838-42, we find that it amounted to an annual saving of 4604 lives during 1860-70; of 13,929 lives annually during 1870-80; and of 21,847 lives annually between 1880-84. The main drainage works were commenced about 1860, and terminated in 1878, and the increase in the saving of life in these consecutive periods may to some extent be taken as a gauge of the effect of the gradual construction and completion of these works. No doubt this London death-rate is far too high, and is an evidence that insanitary conditions still prevail all round us, that the housing of the working classes is still far from satisfactory, and that we are too careless about infectious disease. The Metropolitan Board of Works has never had a clear field for municipal action; yet when we compare the present condition of London with what it was at the Queen's accession, the Metropolitan Board of Works, in spite of the disadvantages of its constitution, will have a grand record to show, in the jubilee year of the Queen's reign, of metropolitan improvements and metropolitan sanitation.

The main principle which guided public administration, both before and during the earlier years of the Queen's reign, may be said to have been that of non-interference, and of allowing free competition to prevail; although, no doubt, some efforts had been previously made to regulate the labour of females and children in Factory Acts.

The practical application of the knowledge derived from the Registrar-General's statistics led to further investigation in particular cases by such men as Dr. Simon, Dr. Buchanan, Sir Robert Rawlinson, and others, and gradually caused a reaction from what may be called the *laissez-faire* system, to the spread of opinion in the direction of control over individual action in the interest of the community generally; and the result was the enactment of the successive laws, for regulating the sanitary condition of the people, which I have enumerated above.

This large amount of legislation is practically little more than the interpretation required by the increase of population, and by the complicated exigencies of modern life, of the common-law maxims, *Prohibetur ne quis faciet in suo quod nocere possit alieno;* and *Sic utere tuo ut alienum non lædas:* that is to say, no man shall do anything by which his neighbour may be injuriously affected, and each person must so use his property and his rights as not to harm any one else.

This common-law doctrine had become practically obsolete, because there was no machinery in existence to enforce it; and the present generation inherited a legacy of misery amongst the poorer classes, owing to the absence of regulations in the building of houses as the towns increased in size, absence of water supply and drainage, and other matters which I have mentioned.

Mr. Mundy's calculations show us what have been the general results of the sanitary improvement of the nation. The death-rate of 1838-42 for England and Wales was 22·07 per 1000; that of 1880-84 was 19·62 per 1000; and the deaths from zymotic disease, which averaged 4·52 per 1000 in the decade 1841-50, were reduced to 2·71 per 1000 in the years 1880-84. It is, however, curious to note that the improvement in urban districts does not appear to have kept pace with that in rural districts, for it appears that whilst the deaths from zymotic disease in certain urban districts have declined from 5·89 per 1000 in the decade 1851-60 to 5·12 per 1000 in the decade 1871-80, the deaths from zymotic disease in rural districts in the same interval have declined from 2·77 to 1·67 per 1000.

In order to form an estimate of the saving of life due to sanitary measures, we may assume that sanitation remained in abeyance, and calculate what the death-rate, according to Dr. Farr's formula, would have been in consequence of increased density of population, and compare that with the actual death-rate; upon this assumption we find that the sanitary improvements only began to tell after the cholera epidemic of 1848-49. In the decade 1841-50, indeed, it appears that the death-rate was actually larger than that due to the increased density of population. But in the following decade, the sanitary improvements began to produce their effect, and this effect has gradually increased. In the decade 1850-60, the annual average saving of lives in England and Wales from sanitary improvements was 7789; in the decade 1860-70, it rose to 10,481; in the decade 1870-80, it was 48,443; and in the five years 1880-84, the average annual number of lives saved by sanitary improvements have been 102,240.

The present social condition of the people affords an equally striking evidence of general improvement. Food and clothing are cheap; the construction of streets and new buildings in our towns are regulated; houses are improved; overcrowding and cellar dwellings are prohibited; the common lodging-houses are controlled. Petroleum affords a brilliant light to the poor in country districts which are beyond the reach of gas or of the electric light, and who were formerly dependent on rushlights. Water supply is rarely deficient; removal of refuse is enforced. But there remains much still to be done. Numbers of the people are still crowded in wretched dwellings; our rivers are polluted and subject to floods; our infectious diseases are not properly cared for.

The main feature of the legislation of the past half-century is the recognition of the principle that when large numbers are congregated together in communities, the duty of preventing injury from this aggregation rests on the community; and if this principle is duly acted on, if in all aggregations of population free circulation of air is encouraged by preventing the crowding together of buildings; if refuse is immediately disposed of, so as to cause no injury to any one; if pure water be provided; if we isolate infectious diseases; and, above all, if we are fortunate enough to retain the blessing of cheap food and clothing, we shall not transmit to our posterity a similar legacy of misery to that which we inherited.

ON THE FORMS OF CLOUDS[1]

THE object of the paper was to explain a theory with regard to the principles that may have the greatest effect in producing the leading cloud-forms. Neglecting occasional and exceptional influences, the author stated that the causes with which his paper dealt might be classed under three heads: (1) the diminished specific gravity of the air when more or less charged with invisible vapour, (2) the differential horizontal motion of the atmosphere, (3) the vertical motion in the atmosphere produced by the heat of the sun expanding the lower air. The first of these was universally recognised as the initial cause of the cumulus, or first-born primary cloud. It was produced when there was so much vapour generated in the lower atmosphere that the vapour-laden layer projected up within the limit of condensation. Of course the vapour below this limit would itself become condensed if cooled in the course of its travels. During the formation of the cumulus, calm was supposed to prevail. When the atmosphere was in motion, its differential horizontal movement produced the first important modification. Retarded by friction and other causes, the lower portion of the cumulus moved more slowly than the upper, and the cloud sheared over into a slanting position, and ultimately became the cumulo-stratus. A young cloud was thus distinguishable from those that had travelled even a short distance. In this climate large well-developed cumuli, though common in summer, were seldom seen in the cold season. The majority of the clouds of the first stage seen here were born in warm latitudes, and, coming as travelled cumuli, showed more or less the condition of the cumulo-stratus. The invisible vapour was subject to this same shearing motion, and far-travelled water-vapour would, on its rising, as it soon does in this climate, to the height necessary for condensation, at once take the shape of the stratus. In the next stratum above, Mr. Glaisher's investigations in his balloon ascents showed a rather rapid change to a drier atmosphere. Here were found the cirro-cumulus, and cirro-stratus. The differential motion of the atmosphere, though diminished, was still an important agent, and produced results that were not possible in the more bulky and dense clouds of the lowest range. When the sun's

[1] Abstract of a Paper read at the Birmingham meeting, 1886, of the British Association, by A. F. Osler, F.R.S. Communicated by Prof. Balfour Stewart, F.R.S.

heat expanded the lower atmosphere, the upper cloud-stratum would be lifted, flattened, and broken into patches, the result being a mackerel sky. Should, however, the expansion in the lower atmosphere take place very slowly, it was possible that the cloud, though thinned, would remain unbroken. Rapid motion of the atmosphere would elongate the cloud in the direction of motion; and, if accompanied by expansion from below, would rupture the cloud into ribs or bars at right angles to the current. If the mass of the cloud were stationary or moving slowly, prominent parts might be drawn out into "mares'-tails."

FURTHER EXPERIMENTS ON FLAME

IN my former paper, published in NATURE, vol. xxxi. p. 272, I showed that there are two classes of continuous spectra, viz. those due to an incandescent precipitate, in which case the flame has the power of reflecting and polarising light; and, secondly, flames that possess no reflecting power, but give a soft continuous spectrum without maxima or minima.

Of this second class is carbonic oxide, which gives, at normal pressures, a fairly bright, and at increased pressure, according to Dr. Frankland, a very bright, continuous spectrum. I have observed its spectrum recently under reduced pressure, using an apparatus similar to that described by Dr. Frankland in his "Experimental Researches," p. 884 *et seq.*

I had considerable difficulty at first in keeping the flame alight at anything like low pressures, and finally adopted a glass jet, of a trumpet shape, increasing very gradually from 1 millimetre to 3 millimetres in diameter, the flame being farther shielded from draughts by a wide disk of cork 10 millimetres below the mouth of the jet.

Experiment 1.—Carbonic oxide was burnt in oxygen. The flame was densest close to the jet, and diminished in brightness

Flame of carbonic oxide burning in oxygen at 60 mm. pressure, with spectrum showing maxima. The continuous spectrum at the bottom is given by the red-hot top of the glass jet.

to the tip, without any definite separation into mantles with a space between. At normal pressure every part of it gave a continuous spectrum.

At about 260 millimetres there began to be a noticeable concentration of the light in the violet and the green in the position of the principal bands of the carbon spectrum. At 120 millimetres the concentration was unmistakable, but the spectrum was still continuous. At 60 millimetres it presented the appearance shown in the sketch. There appeared to be a second maximum in the green—not, however, at all well defined—but the principal maximum was continued upwards into a faint green cloud corresponding to the very faint tip of the flame; this cloud was perfectly isolated, but, unlike the carbon bands, was brightest in the middle.[1] I failed to see a similar cloud over the maximum in the violet, but this might be owing to insufficient light, my pumps being only able to maintain so high a vacuum against a very small flame. Mr. T. Legge, of Trinity, who was with me, observed that the comparative absence of the blue was very remarkable.

My supply of oxygen becoming exhausted, I had to use air. The flame became less bright, and the maxima less marked. By turning it very low, we brought the gauge down to 40 millimetres. The flame still burnt steadily.

Finally, at 60 millimetres pressure, I adjusted the flame to a height of three-quarters of an inch, opened the air-taps, and checked the pumps. The flame increased in brightness and decreased in size to rather more than a quarter of an inch at normal pressure, the spectrum becoming again perfectly continuous.

[1] It is impossible in a woodcut to give a true idea of the extreme faintness of this isolated cloud. It is only visible when the brighter part of the spectrum is hidden from the eye, and the room is perfectly dark.

Experiment 2.—Having the apparatus ready, I repeated Dr. Frankland's experiment of burning coal-gas in air under reduced pressure. He says that "finally, at 6 inches pressure, the last trace of yellow disappears from the summit of the flame, leaving the latter an almost perfect globe of a peculiar greenish-blue tint."

He used a jet contracted at the mouth to 1·5 millimetres. With my much wider trumpet-shaped jet, by turning on more gas I could produce smoke at 160 millimetres so as to blacken the glass chimney. At 120 millimetres the light was noticeably less vivid, the flame having a diluted appearance, but the spectrum showed the usual carbon lines much more sharply defined, the mantles being very much thicker than at normal pressure. With this exception there was no difference caused by the reduction of the pressure to 60 millimetres, and even then, on turning up the gas a little, the ellipsoidal flame became pointed, and the yellow light, giving the incandescence spectrum, re-appeared in the tip of it. It is evident that the trumpet-shaped jet allows carbon to be precipitated in the flame at much lower pressures than the contracted jet. In the same way alcohol heated in a bulb tube burns from the mouth of it with a bright and even smoky flame, whereas it burns from a wick with a blue one.

One phenomenon observed by Dr. Frankland I was disappointed not to see. He says: "Just before the disappearance of the yellow portion of the flame there comes into view a splendid halo of pinkish light forming a shell half an inch thick around the blue-green nucleus; . . . the colour of this luminous shell closely resembles that first noticed by Gassiot in the stratified electrical discharge passing through a nearly vacuous tube containing a trace of nitrogen." He does not speak of having used the spectroscope to determine the nature of this pink glow.

I went considerably below the lowest pressure mentioned in his paper, viz. 4·6 inches, but entirely failed to reproduce it. But I have noticed that very small flames from capillary tubes, observed under a power of 100 in the microscope, are sometimes tinged with rose-colour in the outer mantle, from a very faint trace of sodium orange light mingling with the blue of the soft outer mantle; and I think that the jet he used or the glass chimney may have been sufficiently heated to give a rosy tinge to the flame.

One other point I would call attention to. The appearance of the gas-flame at low pressures is precisely like that of a very small gas-flame under the microscope. The inner mantle appears to be bordered with bright green light, due to the principal green band of the carbon spectrum extending slightly beyond the others. Beyond this, again, comes a zone of violet light due to the band in the violet, and in most cases this extends nearly, if not quite, to the outer mantle. At ordinary pressures this can only be seen with a magnifying-glass, except with a special burner; but the *in vacuo* flame is, as it were, magnified as to its structure, which is thus visible to the naked eye. This fact suggests that flames may in a sense obey Boyle's law, *i.e.* that the space required for complete combustion under given conditions varies inversely as the pressure. I am continuing my experiments.

GEORGE J. BURCH

SOCIETIES AND ACADEMIES

LONDON

Royal Society, November 18.—"The Coefficient of Viscosity of Air. Appendix." By Herbert Tomlinson, B.A. Communicated by Prof. G. G. Stokes, P.R.S.

In the previous experiments by the author on this subject, the coefficient of viscosity of air was determined from observations of the logarithmic decrement of amplitude of a torsionally vibrating wire, the lower extremity of which was soldered to the centre of a horizontal bar. From the bar were suspended vertically and at equal distances from the wire a pair of cylinders, or a pair of spheres. The distances of the cylinders or spheres from the wire were such that the *main* part of the loss of energy resulting from the friction of the air may be characterised as being due to the *pushing* of the air.

Acting on a suggestion of Prof. Stokes, the author proceeded to determine the coefficient of viscosity of air by suspending a hollow paper cylinder about 2 feet in length and half a foot in diameter, so that its axis should coincide as to its direction with the axis of rotation. The cylinder was supported by a light hollow horizontal bar, about 7 inches in length, to the centre of which the vertically suspended wire was soldered. The wire was set in torsional vibration, and the logarithmic decrement determined with the same precautions as before.

The following were the results :—

Vibration-period in seconds		Coefficient of viscosity of air in C.G.S. units, μ		Temperature in degrees Centigrade
3·6038	...	0·00017708	...	12·225
8·8656	...	0·00017783	...	13·075

In these experiments the loss of energy arising from the friction of the air may be characterised as being due to the *dragging* of the air, and it is very remarkable that there should be such close agreement in the values of μ as determined by this and the previous methods. The mean value of the coefficient of viscosity of air obtained by this method is 0·00017746 at a temperature of 12°·650 C., and the mean value deduced from the previous experiments when proper correction has been made for the rotation of the spheres and cylinders about their axes is 0·00017711 at a temperature of 11°·79 C.

November 25.—"On the Structure and Life-History of *Entyloma Ranunculi* (Bonorden)." By H. Marshall Ward, M.A., F.L.S., Fellow of Christ's College, Cambridge, and Professor of Botany in the Forestry School, Royal Indian College, Cooper's Hill.

The author found plants of *Ranunculus Ficaria*, the leaves of which were spotted with white patches; the white patches spread from leaf to leaf, and the disease assumed the nature of an epidemic over a given area under examination. The rise, progress, and climax of the disease were observed both on isolated plants and in the open country, and the nature of the lesions in the leaves was made out. Some plants were found to succumb more rapidly; the evidence supporting this conclusion was given, and the circumstances to which the differences are due explained.

The white disease-spots contain the mycelium of *Entyloma Ranunculi*, and the resting-spores of this fungus (one of the Ustilagineæ) were observed on it. The mycelium is very delicate and septate, and runs in the middle lamellæ between contiguous cells. The white powder on the outside of the disease-spot consists of conidia, very like those of some Ascomycetes. The author examined the anatomical connection between the conidia and the resting-spores, and showed that the conidia really belong to the same mycelium—in other words, the conidia are a second kind of spore of the *Entyloma*.

Even more important is the germination of these conidia: this has not been before observed in any *Entyloma*. The germination was traced step by step, not only on glass slips, but also on the living plant. Artificial infections were made, and it was shown how the germinal hyphæ entered the stomata, and produced a mycelium exactly like that in the disease-spots first investigated; not only so, but the *resting-spores of the Entyloma were produced on this mycelium*, thus placing beyond doubt the connection of the two spores. The time occupied in infection was also determined in many cases. Moreover, all the symptoms of the disease produced by infection with the conidia were as before. The paper was illustrated by diagrams, and specimens of the fungus were exhibited under the microscope.

Mathematical Society, December 9.—Sir J. Cockle, F.R.S., President, in the chair.—Prof. D. Y. Kikuchi, of Tokio, was elected a Member, and Mr. F. S. Macaulay admitted into the Society.—The following communications were made:—The linear partial differential equations satisfied by pure ternary reciprocants, by E. B. Elliott.—Circular notes, by R. Tucker.—The problem of the duration of play, by Capt. Macmahon, R.A.—Note on two annihilators in the theory of elliptic functions, by J. Griffiths.—Mr. Hammond spoke upon the subject of Capt. Macmahon's communication at the November meeting.

Linnean Society, December 2.—William Carruthers, F.R.S., President, in the chair.—The following gentlemen were elected Fellows of the Society, Messrs. J. W. Willis Bund, Arthur Dendy, Anthony Gepp, Tokutaro Ito, F. Krause, F. M. Lascelles, Fred Sander, R. von Lendenfeld, John Samson, Harry S. Burton, A. W. Sutton, and Chas. W. Wilson; afterwards Mr. Geo. Sim was elected an Associate.—The President read a letter from the Rev. M. J. Berkeley, concerning the death of his old and respected co-worker on fungi, Mr. C. E. Broome.—Mr. G. Maw exhibited ten photos of living Narcissi, made in the Riviera in 1870. He afterwards gave a short account of the North African and South Spanish Narcissi as observed by him on a recent visit thither. The *Narcissus papyraceus* extends as far as Fez, in Morocco; south of that *N. sub-Broussoneti* takes its place, and is found from Saffi to Mogador. Incidental allusion was made to the smallest of the white forms of *N. Tazzetta* in the Island of Teneriffe. Of the autumnal species, reference was made to *N. nudiflorus*, which had been lost sight of for half a century, but was re-discovered by Mr. Maw in 1883 in the neighbourhood of Gibraltar, and again recently near Tangier. A hybrid between *N. viridiflorus* and *N. serotinus* was found by him close to Gibraltar, and a series of hybrids between *N. viridiflorus* and *N. elegans* were got in North Morocco. Mr. Maw stated that *N. serotinus* was limited to the south of Spain, and *N. elegans* to the Morocco coast, the latter plant bearing true leaves. He mentioned the abundance in flower and fruit of a small Amaryllid, *Tapeinanthus humilis*, Herbert, as occurring eight miles south of Tangier.—Dr. Day read a paper on the Lochleven trout, which is the form that has been utilised by Sir James Maitland at Howietoun, where the elevation is similar to that of their original home, distant about 25 miles. These fish are known by their numerous cæcal appendages, and up to their fourth or fifth year they are of a silvery gray, with black, but no red, spots. Subsequently they become of a golden purple with numerous black and red spots. Undergrown ones take on the colour of the burn trout. Remove these fish to a new locality, and they assume the form and colour of the indigenous trout. In 1883 a salmon parr and Lochleven trout were crossed, and the young have assumed the red adipose dorsal fin, and the white-edged margins to the dorsal and ventral, also the orange edges to both sides of the caudal—all colours found in the brook trout, but not in the salmon or Lochleven trout. The maxilla in this form not extending to behind the eye, the absence of a knob on the lower jaw in old breeding males and the difference in the fins from those of *Salmo fario* were shown to have been erroneous statements.—A paper was read on Hermann's "Ceylon Herbarium" and Linnæus's "Flora Zeylanica," by Dr. Henry Trimen. The collection of dried plants and the drawings of living ones made in Ceylon by Paul Hermann in the latter half of the seventeenth century possess a special interest as being the first important instalment of material towards a knowledge of the botany of the East Indies; but Hermann himself, who died in 1695, published very little of this material. Some of his manuscripts were subsequently printed by W. Sherard, including a catalogue of the herbarium, as then existing, under the title of "Museum Zeylanica" (1717). This herbarium was lost sight of till 1744, when it was recognised by Linnæus in a collection sent to him from Copenhagen. After two years work at it, Linnæus produced in 1747 his "Flora Zeylanica," in which all the plants that he could determine are arranged under his genera. At that date Linnæus had not initiated his binomial system of nomenclature; but in his subsequent systematic works he quoted the numbers of the "Flora Zeylanica," and thus Hermann's specimens became the types of a number of Linnæus's species, for the most part additional to those in his own herbarium in the possession of the Linnean Society.

Zoological Society, December 7.—Prof. W. H. Flower, F.R.S., President, in the chair.—Prof. Bell exhibited and made remarks on a specimen of a rare Entozoon (*Tænia nana*) from the human subject.—Mr. Tegetmeier exhibited and made remarks on a pair of antlers of a Deer, said to have been recently obtained in the Galtee Mountains in Ireland. They appeared to be those of the Elk (*Alces machlis*).—Mr. Frank E. Beddard read a paper on the development and structure of the ovum in the Dipnoan fishes. The present communication was a continuation of a research into the structure of the ovary in *Protopterus*. The author, besides being able to give a more complete account of the ovarian ova of *Protopterus*, was also able to supplement this account with some further notes respecting the structures observed in the ovary of *Ceratodus*.—Mr. A. Smith-Woodward read a paper on the anatomy and systematic position of the Liassic Selachian, *Squaloraja polyspondyla*. After a brief notice of previous researches, the author attempted an almost complete description of the skeletal parts of *Squaloraja*, as revealed by a fine series of fossils in the British Museum. He confirmed Davies's determination of the absence of the cephalic spine in certain individuals (presumably females), and added further evidence of its prehensile character, suggesting also that the various detached examples afforded indications of one or more new species. The author concluded with some general remarks on the affinities of the genus, and proposed to institute a new family, "Squalorajidæ," which might be placed near the Pristiophoridæ and Rhinobatidæ.—Mr. Sclater, F.R.S., pointed out the characters of an apparently new Parrot of the genus *Conurus*, from a specimen living in the Society's Gardens. The species was proposed to be called *Conurus rubritorquis*.—Mr. F. Day, F.Z.S., communicated (on the part of Mr. J. Douglas Ogilby, of the Australian Museum, Sydney) a paper on an undescribed fish of the genus *Pimelopterus* from Port Jackson, N.S.W., proposed to be named *P. meridionalis*.—Mr. G. A. Boulenger read a paper on the South African Tortoises allied to *Testudo geometrica*, and pointed out the characters of three new species of this group, which he proposed to call *Testudo trimeni*, *T. smithii*, and *T. fiski*.—A second paper by Mr. Boulenger contained some criticisms on Prof. W. K. Parker's paper "On the Skull of the Chameleons," read at a previous meeting of the Society.—Mr. Oldfield Thomas read a paper on the Wallaby, commonly known as *Lagorchestes fasciatus*, and showed that the dentition of this animal was entirely different in character, not only from that of the typical species of *Lagorchestes*, but even from that of all the other members of the sub-family Macropodinæ. He therefore proposed to form a new genus for its reception, to which he gave the name of *Lagostrophus*.—A communication was read from Prof. R. Collett, C.M.Z.S., containing the description of a new Pouched Mouse from Northern Queensland, which he proposed to name *Antechinus thomasi*.

Geological Society, November 17.—Prof. J. W. Judd, F.R.S., President, in the chair.—The following communications were read:—A letter from the Lieutenant-Governor of the Falkland Islands, communicated by H.M. Secretary of State for the Colonies, and printed in NATURE, vol. xxxiv. p. 440.—On the drifts of the Vale of Clwyd, and their relation to the caves and cave-deposits, by Prof. T. McKenny Hughes, M.A., F.G.S. The author divided his subject as follows:—I. Introductory remarks; II. the Drifts, viz. (i.) the Arenig Drift, (ii.) the St. Asaph Drift, (iii.) the Surface Drifts; III. the caves, viz. (i.) the caves themselves, (ii.) the cave-deposits; IV. conclusion. He exhibited a table showing the tentative classification he proposed. II. (i.) The Arenig Drift, he said, might be called the *Western Drift*, as all the material of which it was composed came from the mountains of Wales; or the *Great Ice-Drift*, as it was the only drift in the vale which contained evidence of direct ice-action. He traced its course from the Arenig and Snowdon ranges by striæ on the solid rock and by the included fragments, a large proportion of which were glaciated. There are no shells in this drift. II. (ii.) The St. Asaph Drift might, he said, be called the *Northern Drift*, as it was the deposit in which fragments of north-country rocks first appeared; or the *Marine Drift*, as it was, excepting the recent deposits at the mouth of the estuary, the only drift in the vale which showed by its character and contents that it was a sea-deposit. It contained north-country granites, flints, and sea-shells, of which he gave lists. Most of them are common on the adjoining coast at the present day; a few are more northern forms. None of the rocks are striated, except those derived from the Arenig Drift (i.). II. (iii.) The Surface-Drifts included the older and newer alluvia of the rivers, the Morfa Rhuddlau Beds or estuarine silt, the recent shore-deposits or Rhyl Beds, and all the various kinds of deposits known as talus, trail, rain-wash, head, run-of-the-hill, &c., of which, in so long a time, very thick masses have accumulated in many places. He explained some methods of distinguishing gravels according to their origin. Turning to the subject of caves, he thought they should be careful not to confound (III. i.) the question of the age and origin of the caves themselves with (III. ii.) that of the deposits in the caves. He then described some of the more important caves of the district, explaining the evidence upon which he founded the opinion that the deposits in Pontnewydd Cave were post-glacial palæolithic. He arrived at the same conclusion with regard to the deposits in the Ffynnon Beuno Caves. Combating the objections to this view which had recently been urged, he pointed out that the drifts associated with the deposits in those caves cannot have been formed before the submergence described under II. (ii.), because they contained north-country fragments and flints, and that, even if they were of the age of the submergence, they would not be pre-glacial; that they cannot have been formed during the submergence, as the sea would have washed away the bones, &c., from the mouth of the cave, and its contents must have shown some evidence of having been sorted by the sea. He considered that the greater part of the material that blocked the upper entrance of the upper cave belonged to the surface-drifts described under II. (iii.), and were, as they stood, almost all sub-aërial. He further pointed out that, so far as palæontologists had been able to lay before them any chronological divisions founded on the Mammalia, the fauna of the Ffynnon Beuno Caves agreed with the later rather than with the earlier Pleistocene groups.

Middlesex County Natural History Society, November 16.—Dr. Archibald Geikie, F.R.S., in the chair.—A paper was read by Mr. Sydney T. Klein, entitled "Thirty-six Hours' Hunting amongst the Lepidoptera and Hymenoptera of Middlesex, with Notes on the Methods adopted for their Capture." The especial object of the paper was to show how much good work could be done in a short time and within a small space—the time being made up by an hour or so each evening, and the space being the author's garden at Willesden. Detailed observations on the methods of enticement and capture—such as the rearing of special food-plants, sugaring, bright lights, &c.,—were entered into, and a list of the Noctuæ captured was read. Mr. Klein stated that he had taken over 170 species in the short time at his disposal, and had noticed, on an average, 500 or more moths on each occasion. With regard to the Hymenoptera, both mason and leaf-cutter bees had established themselves in his garden, and some interesting observations on their habits and economy were given. A large collection, containing specimens of every insect taken, was exhibited, together with the ichneumons peculiar to several of the species; a torpid mason-bee, which was restored to activity by breathing; and cells of the queen of the Ligurian honey-bee. A discussion followed, in which the Chairman joined; and, with a few remarks by the other members who had brought exhibits, a vote of thanks to Dr. Geikie brought the meeting to a close. Another paper, "On the Flora met with on the occasion of the Highgate Excursion," by Dr. Henry Wharton, was postponed till the December meeting.

CAMBRIDGE

Philosophical Society. Oct. 25.—Annual General Meeting.—Prof. Foster in the chair.—The following were elected Officers and new Members of Council for the year:—President: Mr. Trotter; Vice-Presidents: Prof. Babington, Prof. Adams, Prof. Foster; Secretaries: Mr. Glazebrook, Mr. Vines, Mr. Larmor; new Members of Council: Prof. Liveing, Mr. Forsyth, Mr. Marr, Mr. Pattison Muir.—Mr. Trotter then took the chair, and the following communications were made to the Society:—On Lagrange's equations of motion, by Mr. J. C. McConnel. The paper contains a proof of Lagrange's equations founded on that in Lord Rayleigh's "Theory of Sound," with some remarks on the proof given in Maxwell's "Electricity and Magnetism."—On the potentials of surfaces formed by the revolution of limaçons and cardioids about their axes, by Mr. A. B. Basset. The potential of a spheroid can be expressed in terms of a series of spheroidal harmonics. From this by inversion with respect to a focus the potential of limaçon is found, while that of a cardioid is obtained from a paraboloid either in a similar manner or by treating it as the limiting case of the spheroid.—An attempt to explain certain geological phenomena by the application to a liquid substratum of Henry's law of the absorption of gases by liquids, by Rev. O. Fisher. The author supposes that a liquid substratum exists beneath the earth's crust, and that this consists of fused rock holding gas, chiefly water above its critical temperature, in solution. This water is supposed to be that which is given off so largely in volcanic eruptions. If such be the constitution of the substratum, the reactions between it and the crust will largely depend on it, and also the tidal effects. The problem is worked out in the paper, and numerical results, which accord fairly with observed facts, are obtained.—A new method of determining specific inductive capacity, by Mr. L. R. Wilberforce. The author briefly described the method, which consisted in the comparison of the directive couples upon two spheroids, the one made of the dielectric to be investigated, and the other of some conducting material, when they were placed in a uniform electric field. He further indicated certain theoretical considerations with regard to the eccentricities of the spheroids and their manner of suspension, and stated a general theorem relating to the mechanical effect due to such a field upon a body of any material or form.

PARIS

Academy of Sciences, December 6.—M. Daubrée in the chair.—Reply to M. de Lapparent's note of November 22, on the conditions determining the form and density of the earth's crust, by M. Faye. The conclusions of modern physicists regarding the uniform flattening of both terrestrial poles are vindicated against M. de Lapparent's captious objections. The general charge that the work of geodesy is far from completed is admitted; but it is pointed out that, in order to continue this work, it is not necessary to sweep away the secure results already obtained; it will be safe to prosecute it on the safe lines already laid down by Sabine, Freycinet, Foster, Clarke, Lütke, and other eminent men of science.—Action of manganese on the phosphorescent property of carbonate of lime, by M. Edmond Becquerel. The experiments here described place in a clear light the action of manganese, explaining how the carbonate of lime derived from the solution of Iceland-spar in pure hydrochloric acid always leads to preparations of orange phosphorescent sulphurets, while the phosphorescent matter is always bright green when the carbonate of lime used in the preparation is aragonite.—On the nitric substances of vegetable soil, by MM. Berthelot and André. A first series of experiments is here described, which have been carried out in the presence of diluted hydrochloric acid for the purpose of determining the chemical constitution of the nitric substances found in all vegetable soils in association with carbon, hydrogen, and oxygen, and almost absolutely insoluble.—On the composition of cider, by M. G. Lechartier. A quantitative analysis is given of the various ciders at present consumed in Paris, and coming chiefly from Normandy and Brittany. The results show an average proportion of alcohol lying between 5·1 and 9·40 per cent.—On the red fluorescence of alumina, by M. Lecoq de Boisbaudran. These experiments show that the presence of chromium appears to be indispensable for the production of the red fluorescence of alumina. There seems to be a complete analogy between the parts played by chromium and all other active substances, such as Mn, Bi, $Z\alpha$, $Z\beta$ or Sm.—Report made, in the name of the Section of Physics, in reply to a letter of the Minister of Public Instruction, Fine Arts, and Worship on sundry questions connected with the establishment of lightning-conductors on the buildings of the Lyceums (Commissioners: MM. Becquerel, Berthelot, Cornu, Mascart, Lippmann, and Fizeau). The report considers it indispensable for complete safety to have all iron roofs, doors, sashes, pipes, &c., carefully connected with the general apparatus usually attached to these buildings as protections against electric discharges.—On the fundamental principles of the higher geometry, by M. A. Mouchot. To generalise the figures of geometry by assigning them well-defined imaginary points, and then to prove that the algebraic symbols express all the relations of magnitude or position between the elements of these figures, is the double problem which has engaged the attention of the author for the last thirty years, and a rational and complete solution of which is now submitted to the Academy.—On certain problems in which are considered, on a plane curve, arcs of the same origin traversed in the same time as the corresponding chords, by M. G. Fouret.—On a new testing exploder ("exploseur-vérificateur") of quantity and tension, by MM. Louis de Place and Bassée-Crosse. This apparatus consists of a moist pile of the Place-Germain system, an induction bobbin, and a telephone. It is described as very handy, portable, and durable, advantageously replacing the exploders of quantity and the exploders of tension. It also verifies the circuits at any given moment without danger of premature explosion.—Calorimetric researches on the specific heats and changes of state at high temperatures, by M. Pionchon. In this first communication the author gives, in tabulated form, the results of his calorimetric studies for silver, tin, iron, nickel, and cobalt. His experiments fully confirm the opinion already announced by M. Berthelot on the so-called law of Dulong and Petit.—On the tensions of vapour of solutions made in ether, by M. Em. Raoult. The tensions of vapour for the solutions here determined by Dalton's method show that the molecular diminutions of tension are always comprised between 0·67 and 0·74, with a general average of 0·71, whatever be the composition, chemical function, and molecular weight of the substances held in solution.—Researches on the bi-metallic phosphates and allied salts, and on their transformations, by M. A. Joly.—Saturation of normal arsenic acid by magnesia, and formation of ammoniaco-magnesian arseniate, by M. Ch. Blarez. These researches on the formation of the arseniates of magnesia and of ammoniaco-magnesian arseniate have been undertaken for the purpose of completing the author's studies on the saturation of normal arsenic acid.—On the phenomena attending the heating and cooling of cast steel, by M. Osmond. In continuation of his studies of these phenomena between the normal temperature and 800° C. the author here gives the results of his researches brought up to 1200° C.—On the influence of silicium on the state of the carbon in pig-iron, by M. Ferdinand Gautier. The experiments already carried out by Messrs. Stead and Wood, of Middlesbrough, are here repeated under somewhat altered conditions and with analogous results.—On the water of combination of the alums, by M. E. J. Maumené.—Heat of neutralisation of the meconic and mellic acids, by MM. H. Gal and E. Werner.—A contribution to the study of the fossil fruits of the Eocene flora in the west of France, by M. Louis Crié.—On the diseases of the olive, especially tuberculosis, by M. L. Savastano. —On the phenomenon of the green ray, by M. de Maubeuge. The author's repeated observations of this well-known phenomenon, both at sunset and sunrise under varying atmospheric conditions, lead him to conclude that it is really objective, and not merely a subjective sensation.—The Indo-European Canal and the navigation of the Euphrates and Tigris, by M. Emile Eude. It is suggested that with a capital of about 60,000,000*l.* a canal available both for navigation and irrigation might be constructed from the Mediterranean to the Persian Gulf, shortening the route to India by six days.

CANAL AND RIVER ENGINEERING

The Principles and Practice of Canal and River Engineering. By David Stevenson. Revised by his Sons, D. A. and C. A. Stevenson. Third Edition. Pp. xiv. + 406, and 18 Plates. (Edinburgh: A. and C. Black, 1886.)

THE fact of this work having reached a third edition shows its appreciation by the public. The title, however, indicates a wider scope than that actually embraced. Thus only 65 pages are given to canals, and these only for navigation; no mention is made of the very large subject of irrigation-canals (surely a passing notice of the reason of this omission was required). In this short compass (30 pages given to barge canals, 35 pages to ship canals), part of which is an historical sketch, it is of course impossible to give much constructive detail. Thus no details or sketches are given of most of the appliances needed for canals, *e.g.* locks, turbines, lifts, waste-weirs, &c. The two chapters on canals are otherwise unsatisfactory; *e.g.* 14 pages devoted to the Suez Canal consist chiefly of extracts from Reports made in 1863 and 1870: much of this now purely historical matter might have been with advantage replaced by later information.

The remainder of the work (331 pp.) is devoted to river improvement. And this part of the work is of great value and interest, especially where accounts are given of some of the numerous successful instances of improvements of estuaries effected by the author and the revisers themselves. The great help of a large rise and fall of tide to a commercial port situate in the tidal portion of a river, viz. in aiding vessels coming to and leaving the port, is first explained; the pre-eminent importance of this tidal action to England is evident. As might be expected, then, the greater part of the work is devoted to the improvement of the tidal portion of rivers such as those of the British Isles.

Two useful chapters (92 pp.) are given to the observations required for a project for such work, *e.g.* tidal phenomena, soundings, current-velocities, discharges, salinity, &c. In quoting Cunningham's instrument (twin balls, sunk one to ·211 and one to ·789 of the depth) for measuring mean velocity past a vertical *at one operation*, it should be stated that the two balls should be *alike in all respects*. Fourteen pages are given to the subject of "under-currents"; one instance is quoted (p. 135) of a velocity of 4 miles per hour at 50 feet depth measured with a "double-float," when the surface-velocity was only 1·8 miles per hour. This is one of the best instances (known to the reviewer) of the excellence of the "double-float" (when well designed) for sub-surface velocity-measurement; several other good instances are quoted. These should surely convince those who condemn the "double-float" as useless for such work. The natural defects of most (tidal) rivers in their tidal reaches are detailed as the presence of a "bar" at the mouth, of hard veins of gravel, rock, &c., obstructing the water-way, of extensive mud or sand flats through which the deep channel is ever shifting, &c.

The explanation of the cause of a "bar" at a river mouth now generally accepted, viz. as being really a submerged part of the "beach" of the outer shore-line, produced from the sea by the action of the waves (not from the alluvium brought down by the river), appears to have been first proposed by the author of this work in 1842. This suggests the treatment usually found successful in tidal rivers, viz. prolonging the fairway of the river, by piers, seawards into the deep water beyond the reach of the waves which produce the beach. And it is seen that this will fail in effecting a permanent cure in deltaic rivers, in which the gradual advance of the delta will reproduce shoal-water outside the ever-advancing mouths, in which the waves will therefore reproduce a bar.

The ideal improvement to be aimed at in the tidal part of a river is explained to consist chiefly in introducing increased tidal scour by removing obstruction to it (such as bars, &c.), and by confining its action under half-tide to a definite channel. These changes accelerate the propagation of the tidal wave, and decrease the tidal current, thereby giving (sometimes greatly) increased depth of water, not only over the bar at the mouth, but throughout the tidal reaches, and also prolong the duration of the tidal effect. The benefit of these results to navigation is obviously very great.

It is shown that jetties, groynes, &c., projected from the banks of a stream for confining the fairway to a defined channel are very uncertain in their effects. The course recommended in general is the use of low parallel training walls for confining the course of the river under half-tide to a single definite channel, low enough to be covered at half tide. Several interesting instances are given of the failure of the jetties, &c., and success of the low parallel wall system. After this treatment silting will generally occur in places behind the training walls, increasing gradually till marsh-land is produced; after which it is often possible to reclaim some of the raised land: but it is stated that it seldom pays to do this in British rivers until the silting has raised the land to the level of ordinary spring-tides. A most useful practical rule is proposed, that reclamation work should only be undertaken as part of a large general scheme of improvement of a navigation, and never be permitted to the desultory self-interested efforts of private riparian proprietors.

A short chapter (9 pp.) is given to the effect of bridge on navigable rivers. In highly civilised countries this is now a question of rapidly increasing importance. It is shown that the interests of the bridge constructors, especially in the case of railways, are generally adverse to those of the navigation. Of course the subject cannot be much developed within 9 pages. But a short description (with plate) of the railway swing-bridge over the Ouse has been included.

An excellent account is given (31 pp.) of the various processes of dredging and excavating, with a description of some of the most recent machines, and an analysis of the cost of the work.

It will be seen that on the whole this treatise is an excellent account of the principles and practice of river engineering, to the successful practice of which its able authors have so largely contributed.

ALLAN CUNNINGHAM, Major R.E.

ALPINE WINTER

Alpine Winter in its Medical Aspects: with Notes on Davos Platz, Wiesen, St. Moritz, and the Maloia. By A. Tucker Wise, M.D., &c. Third Edition. (London: Churchill, 1886.)

THIS work possesses a fourfold interest. The meteorologist will find in it an account of the Swiss Alpine climate in winter, with full and careful records of the author's observations, which occupy one-fourth of the whole volume. The sanitary engineer may here obtain a clear account of the first successful attempt that has been made to warm and ventilate a large building on strictly scientific principles during the months when the temperature of the air frequently falls below zero. To the physician the book will serve as a guide in advising his patients on the subject of the Alpine health-resorts, in the determination of suitable cases, the peculiar advantages of each place, the duration of stay, and the time to leave—giving, as it does, the physiological effect of each of the peculiar elements of a winter climate at high elevations. Lastly, all those who, either from necessity or from choice, have arranged to pass part of the winter in the Engadine or at Davos, can learn from these pages how to plan and prepare for their outfit and journey, the best routes by which to travel, how to avail themselves of the advantages of the winter health-resorts of these parts, and how to minimise the drawbacks or dangers connected with this system of treatment.

The principal places which Dr. Tucker Wise describes are Davos-am-Platz, Wiesen (a warm bright hamlet six miles lower down the stream), St. Moritz (now almost as renowned for the winter effect of its atmosphere in consumption as of its waters in debility), and, lastly, the Maloia. As the author has now taken up his residence at the Maloia *Kursaal*, it is only natural that he should devote a considerable part of his book to it. It is this hotel which presents, as we have said, the earliest and one of the greatest efforts in the direction of artificial heating and ventilation in the Alps. Nature and art meet at the Maloia in the most interesting combinations. Without the *Kursaal* there is the brilliant, dry, calm, absolutely pure atmosphere of the Upper Engadine, "laden with balsamic vapour from the pines"; within its walls there is every appliance which science can suggest to preserve the purity and maintain the proper temperature of the respired air, constantly liable as it is to dangerous contamination by the residents, who to the number of several hundreds can be accommodated in its apartments. The elaborate system adopted for warming and circulating the admitted air is fully explained in this work with the aid of a series of large diagrams. The air, drawn from the outside on the basement, is made to pass over a series of *batteries*, consisting of steam-pipes inclosed in a case, by means of which it is raised to a temperature of 50° C., whilst it is at the same time mixed with a due proportion of watery vapour. The ascending power of the heated air raises it to the rooms above, which it enters at a rate sufficient to change the atmosphere every two or three hours. To extract the used-up air there are two tubes of exit, which finally communicate with an iron casing around the main flue of the furnaces, which thus acts as the extraction-shaft. Not only is every room thus warmed and ventilated, but the atmosphere of any particular chamber can be medicated at will by placing an antiseptic agent in the air-tube supplying it. A plan has also been adopted in the *Kursaal* of introducing ozone into the building by means of the electricity used for lighting, the motor force for the machines being a fall on the River Inn. "The ozoniser draws off its electricity from the main current of the incandescent lights. After passing through an inductorium, an induced current of about 200,000 volts is obtained, and distributed over the surface of numerous glass plates coated with tin-foil. The method employed is an imitation of the natural process which takes place in the atmosphere,—the production of ozonised air by electricity in a state of high tension. Air is forced between the glass plates and through the ozoniser by means of a 'blower,' driven by a water motor."

To those for whom any of the subjects which we have selected for comment may possess practical interest we would say: "Do not be satisfied with reading Dr. Tucker Wise's book; go and see for yourselves on the spot." There is no more enjoyable or more successful holiday in our dark and dreary winter for the jaded dweller in large English towns than a few weeks spent in the sparkling air of St. Moritz or the Maloia. B.

OUR BOOK SHELF

Magnetic Horizontal Intensity in Northern Siberia. By A. C. von Tillo. From the *Repertorium für Meteorologie*, Band x., No. 7. (St. Petersburg, 1886.)

THE maps of lines of equal magnetic horizontal intensity which have been published during recent years have been more or less defective in that part of Siberia lying north of the 60th parallel of latitude, partly arising from want of fresh observations, but more directly from insufficiency of data respecting the secular change of that element.

The present paper, with its accompanying map, is intended to remedy these defects, as far as is at present possible, for the epoch 1880. For this purpose, every observation since 1828, when Hansteen and Due started on their well-known magnetic survey, has been collected in a Table A, and the best values obtainable of the secular change in a Table B. As represented in the latter table, the secular change is of so moderate an amount, that every observation during the interval 1828-84 may, without large error, be considered available for combination in one map for 1880.

This has been accordingly done, and a map drawn, showing lines of equal horizontal intensity expressed in Gaussian units, the scale being in conformity with that of the maps published in the *Annalen der Hydrographie*, Heft vii., July 1880.

Amongst the most important recent observations recorded in Table A are those of F. Müller in the *Olenek* Expedition of 1873, and of the voyage of the *Vega* in 1878-80, and as a whole the paper and map may be taken as a valuable contribution to terrestrial magnetism. The secular change, however, still remains a quantity requiring much more accurate results than those hitherto obtained for Siberia, and such as are derived from prolonged observation in one spot, it being now well known that a change of position of a few feet often allows an element of error to enter, caused by local magnetic disturbance.

The Ordnance Survey of the United Kingdom. By Lieut.-Colonel T. Pilkington White, R.E. (London and Edinburgh: Blackwood and Sons, 1886.)

THIS is a slight sketch, most of which has already appeared in *Blackwood*. Carefully as the author has kept himself to what in an account of many businesses would be "dry detail," avoiding all anecdote, either biographical or operative, in illustration of work done, it is still a most interesting little book to all who have seen the Ordnance surveyors and their assistants about the town or country, or even their mark upon the stone, brick, or other permanent material. Few indeed will there be who will not find their own special taste ministered to either in the account of the measurement of a base-line with its verification by astronomical observation, by trigonometrical calculation, and by exact chain measurement of a known proportion of it, with the record of frequent triumphs of marvellous correctness; or, again, in the exactness required and gained in the standard measure, with the careful comparison of the English measure with the corresponding foreign standards by which to unite our observed measurements with those of other countries. Such histories give confidence in the trustworthiness of the maps when published, to the surveyor, and hence to both buyer and seller of land. Distant, we hope, is the time when they will be of value to military commanders for choosing ground and availing themselves of the various features of the country, so well laid down that a practised eye like that of Prof. J. Geikie can detect different geological formations by the shading of the hills! Still, this military value is an argument for the frequent revision of maps in which even trees are marked down that would form an important item in strategical movements. We must sympathise in the hope strongly expressed here that the present accomplished staff may be permanently kept together in periodical revision of these maps. Their value after a space of time to the scientific geologist wishing to compute rates of denudation or deposition is invaluable; while a much more potent argument to this generation probably is that much of the whole surface of Lancashire and Yorkshire has been changed by the hand of man during the forty years which have now elapsed since that district was surveyed, and perhaps the environs of London still more completely during the twelve to twenty-one years since the maps of them were published. Certainly no one who reads the numerous labours to which they have turned their hands, some of them seeming little connected with their regular work, can have any fear of idleness on the part of the staff of this department.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

The Cambridge Cholera Fungus

In No. 247, vol. xli. of the *Proceedings* of the Royal Society, just published, there is a preliminary report on the pathology of cholera asiatica, by Messrs. C. Roy, J. Graham Brown, and C. S. Sherrington, in which these gentlemen describe and figure the occurrence, in the tissue of the intestinal mucous membrane of persons dead of cholera asiatica, of hyphæ or mycelial threads and "granules." Messrs. Vines and Gardiner have, we are told, declared these to be Chitridiaciæ. We are further informed that these Chitridiaciæ were found by Messrs. Roy, Brown, and Sherrington in the intestinal mucous membrane of the twenty-five cases of cholera they have examined, as also in the kidney, and in the blood-vessels of some of these cases.

I have no hesitation in saying that I consider these statements are based on error. What these gentlemen have seen and described is nothing less or more than the hyphæ or mycelial threads of common mould (probably aspergillus), which, during preserving of the material, have grown from the free surface into the tissues. I possess a large number of specimens made of the diseased intestine, lung, kidney, liver, and skin of various animals and men, in no way connected with cholera asiatica; in many of them I find the exact appearances described and figured by these gentlemen, viz. mycelial threads of precisely the same size and appearance as those above mentioned. They are seen to penetrate from the surface, where they form a copious dense mycelium, into the depth to various degrees. I possess sections through the mucous membrane of the intestine of the calf, of the mouse, of the guinea-pig, and of man, in which these hyphæ have penetrated as deep as the submucous tissue; in the lymphatics of this part they were very abundant. Similarly, I have specimens of the lung of calf, cow, and guinea-pig, where the growth of the mycelial threads can be traced from the pleural surface into the lung-tissue; in the lymph-vessels of the intertubular septa they are very numerous, and possessed of those knob-shaped outgrowths figured and described by Messrs. Roy, Brown, and Sherrington. I have also specimens of the ulcerated skin of calf and cow, where these hyphæ can be traced as deep as the subcutaneous tissue. Into the kidney and the mesenteric lymph-glands they also penetrate, but less than in the above organs, probably owing to the greater density of the tissue.

Now, in all these instances, these tissues had been preserved during and over the summer months; they were examined after three or more months' preservation, and the sections were stained in methylene-blue. But I must state, also, that the same tissues had been examined fresh, and after a few weeks' hardening, and in none of them had any mycelial growth been present. It is a fact, as is pointed out by Roy, Brown, and Sherrington, that methylene-blue brings the threads out more easily and better than other aniline dyes.

There can be absolutely no doubt about the identity of the Cambridge "Chitridiaceæ" with the hyphæ of the common mould found in the sections of my non-choleraic specimens. What Messrs. Roy, Brown, and Sherrington describe as "granules," connected by delicate filaments, are, in most instances, filaments and branches seen in optical or real transverse section; with careful fine adjustment of the microscope this can be without difficulty ascertained.

Messrs. Roy, Brown, and Sherrington assume that their Chitridiaceæ have been overlooked by others who have examined cholera intestines, because methylene-blue had not been used. This assumption is entirely wrong, because methylene-blue, as Löffler's (or alkaline) solution and in other modifications, had been used by many investigators. While in India, I largely used it for the staining of sections, fresh, and after a few days' to a few weeks' hardening, and I know, as a positive fact, that the German Commission have, in Egypt, in India, and after their return to Berlin, largely used this dye. But in not one single case have they or have I found anything of mycelial threads either in the intestinal mucous membrane or in any other organ. The only difference between Messrs. Roy, Brown, and Sherrington on the one hand, and all other investigators on the other, is this, that while the former kept their material bottled for some months (*vide* their report, p. 177), the latter examined theirs fresh or after short and careful hardening. That this is the real explanation of the difference of our results is proved by the following:—A bottle containing bits of choleraic intestine preserved by me in Calcutta, and brought over to England, was opened many months after; sections were made of the intestine, and stained in methylene-blue. On the free surface of the mucous membrane was found a dense plexus of mycelial threads of common mould, from which threads of various thickness had singly grown into the tissue to the depth of the submucous tissue.

Of the same choleraic intestine numerous sections had been made in Calcutta, fresh, and after a few weeks' hardening; these had been stained in methylene-blue, but in none of them is there any trace of mycelial threads. I have these sections at present in my possession; and, while they show that there is a complete absence in the mucous membrane of mycelial threads, the others, viz. those made of the same intestine, and after the same method, but after having been kept bottled for some months, show beautiful mycelial threads pervading the mucous membrane through all depths.

These threads, in their course, thickness, mode of branching, in the character of the bud-like sprouts, in short in all their morphological characters, are unmistakably identical with the hyphæ found in specimens of the non-choleraic intestine, lung, skin, kidney, mesenteric glands, preserved, as stated above, over the summer.

In conclusion I wish to say that I shall be most happy to place at the disposal of Messrs. Roy, Brown, and Sherrington, as also of Messrs. Vines and Gardiner, the materials or sections, mounted and stained, of the various non-choleraic tissues in which are present the mycelial threads of common mould identical with the Cambridge cholera fungus. E. KLEIN

The Longitude of Rio

MAY I ask for a few lines in which to correct an erroneous impression naturally made by a sentence in my recent paper on "Ten Years' Progress in Astronomy," which you have honoured me by reprinting in NATURE. The sentence relates to the longitude of Rio; and although it does not really assert that the error in this longitude was first detected and corrected by our American naval officers, yet I must frankly admit that the connection and form of expression are such that this would be the natural, though incorrect, inference. The fact is that Admiral Mouchez and his coadjutors in the French Navy had already, by their chronometric and other work, brought the uncertainty to very narrow limits (say ± 2s.) before the telegraphic campaign of the Americans. The history of the case is peculiar, but too long to be given here: it affords an excellent example of the uncertainty of longitudes based on lunar observations.

The misleading form of the sentence is due to a little carelessness on my part in cutting down the much more extended statement I had made in the first draft of the paper. The available limits of time and space compelled me to compress my material to the utmost.

I cheerfully make this correction in justice to Admiral Mouchez, who has called my attention to the matter.

Princeton, N.J., December 9 C. A. YOUNG

An Error in Maxwell's "Electricity and Magnetism"

MANY of your readers will be aware that Maxwell (ii. § 544) deduces the equations of induction of currents from the laws of electro-dynamics with the aid of the principle of energy, using a proof taken from Helmholtz. I find that this proof is erroneous; and, as a point of considerable physical interest is involved, I wish to call attention to the error in your columns.

We suppose two circuits carrying currents to be moving relatively to each other. Let R_1, R_2 be the resistances, I_1, I_2 the currents, A_1, A_2 the electromotive forces of the batteries, and $-I_1 I_2 \frac{dV}{dt}$ the rate at which work is done by the external forces which are moving the circuits. Then $A_1 I_1 + A_2 I_2$ is the rate at which the batteries are doing work, and $R_1 I_1^2 + R_2 I_2^2$ is the rate at which energy is being changed into heat in the wires. So Maxwell says we have—

$$A_1 I_1 + A_2 I_2 - I_1 I_2 \frac{dV}{dt} = R_1 I_1^2 + R_2 I_2^2 \quad . \quad . \quad (1)$$

and it is this equation that is wrong. He has omitted to take into account the change in the electro-kinetic energy which is taking place. If, for instance, the two batteries were suddenly thrown out of the circuits, the quantity of heat that would afterwards appear, either in the wires or in the form of sparks, would depend on the relative position of the circuits. And the energy that would then appear as heat previously exists in the form of electro-kinetic energy.

Let M be the coefficient of mutual induction. Then, if we neglect the rate of change of the currents, the rate of increase of the electro-kinetic energy is $I_1 I_2 \frac{dM}{dt}$. So, instead of (1), we should write—

$$A_1 I_1 + A_2 I_2 - I_1 I_2 \frac{dV}{dt} = R_1 I_2^2 + R_2 I_2^2 + I_1 I_2 \frac{dM}{dt} \quad .. (2)$$

If we assume the accepted equations of induction of currents, viz.—

$$\left.\begin{aligned} A_1 &= R_1 I_1 + I_2 \frac{dM}{dt} \\ A_2 &= R_2 I_2 + I_1 \frac{dM}{dt} \end{aligned}\right\} \quad . \quad . \quad . \quad . \quad (3)$$

neglecting, as before, the rate of change of the currents, we see that $\frac{dM}{dt} = \frac{dV}{dt}$.

And therefore the decrease of electro-kinetic energy is equal to the work done by outside mechanical forces on the system. This result was long ago obtained by Sir William Thomson, as is indeed noticed by Maxwell in this very article.

Notwithstanding the use of the incorrect equation (1), Maxwell obtains a correct result. In fact, he falls into a second error which exactly compensates for the first. He supposes I_2 to be very small compared with I_1, and says that we may then with sufficient accuracy put $A_1 = R_1 I_1$ in (1). But by (3) we see that the term thus neglected is $I_1 I_2 \frac{dM}{dt}$, which is not negligible.

As I have not had access to Helmholtz' original memoir, I cannot say whether Maxwell has correctly transcribed his proof.

JAMES C. MCCONNEL

St. Moritz, Engadine, Switzerland

Seismometry

IN reply to my letter answering Prof. Milne's assertions (NATURE, Nov. 25, p. 75), Mr. T. Gray (his associate in seismometric work) says nothing in support of these, but attacks me on two distinct and quite irrelevant issues. The tone of Mr. Gray's letter (Dec. 9, p. 126) is unusual: as to that no answer is necessary; but the two questions of fact raised by him require reply.

(1) Mr. Gray writes:—"He [Prof. Ewing] says, or leads one to infer, that he introduced horizontal pendulums in seismology." On the contrary, what I *have* said (in my memoir on "Earthquake Measurement," Tokio, 1883, p. 21) is this:—

"It appears that the earliest attempt to apply the horizontal pendulum to the measurement of earthquake-motions was made by Prof. W. S. Chaplin, of the University of Tokio, about 1878. His apparatus consisted of a wooden rod, free to turn about a vertical axis, and carrying at its end a rigidly attached block. It was intended that the motion of the earth should be recorded by a tracing-point fixed to the block, writing on a smooth surface fixed to the earth below it. There was no multiplication of the motion, and either for this reason, or because friction was not sufficiently avoided at the joints and pointer, no results were ever obtained, and the apparatus was abandoned."

The passage Mr. Gray alludes to as having been "read in my presence" was a casual reference by Prof. Milne to these unsuccessful experiments. Prof. Chaplin, their author, has himself written to me:—

"I certainly think you were the first to use successfully a seismograph depending on the principle of the horizontal pendulum. I believe the records obtained by you with this seismograph were the first obtained in Japan (and probably in the world) which showed the motion of the earth during an earthquake from beginning to end of the shock. I cannot better mark the effect which the first record produced than by relating my own experience. I was, up to that time, working on an instrument for determining the velocity and direction of an earthquake; and my design was founded on the idea that an earthquake began with a sudden and violent *shock*. Your records showed (I believe for the first time) that an earthquake often began with an almost imperceptible motion, which increased in amplitude and might have many maxima; hence my machine would have been useless had I completed it."

What I do claim in this matter is that I succeeded in constructing the earliest successful seismograph capable of making absolute measurements of the horizontal motion throughout an earthquake, in conjunction with the time, and giving records from which the amount, direction, velocity, and acceleration of the successive movements could be, and *were*, for the first time determined. The earliest records, referred to by Prof. Chaplin, were obtained in November 1880, and are described in the *Transactions* of the Asiatic Society of

Japan for that year (vol. ix. p. 40). Further, in publishing an account of the horizontal pendulum seismograph, I pointed out that the way to get a steady-point with respect to one component of earthquake-motion, is to pivot a body in nearly neutral equilibrium, with the corresponding kind of freedom, and to use the centre of percussion as the steady-point, the steadiness of the steady-point being increased, if need be, by pivoting a second mass there. So far as I am aware, this obvious principle was first explicitly recognised and applied in my horizontal pendulum seismograph; and on this point I shall appeal from Mr. Gray of 1886 to Mr. Gray of 1881:—

"I believe the first time special attention was paid to the application of this well-known dynamical principle to seismometers is to be found in a paper communicated by Prof. Ewing to the last meeting of this Society" (T. Gray, *Trans. Seis. Soc. Jap.*, vol. iii. p. 5).

(2) Mr. Gray's second charge is that I am using his vertical motion seismometer without acknowledgment. I am not using his instrument; and I have acknowledged fully his service to seismometry in this connection. A horizontal bar, loaded at one end and held up by a spring, was used for vertical motion by the British Association Committee at Comrie in 1842. In 1881, Mr. Gray, holding the bar up by a long spiral spring, made the suspension astatic by adding a trough or tube containing mercury (*Trans. Seis. Soc. Jap.*, vol. iii. p. 137). After seeing this, I devised another and simpler method of making the suspension astatic, and in describing it I said:—

"At a recent meeting of the Society, Mr. T. Gray described a seismometer for vertical motion, in which the problem of supporting a heavy mass, so that it should be free to move vertically and yet remain in neutral equilibrium, was for the first time (so far as I am aware) successfully solved" (*Ibid.* p. 140).

My method is entirely different from Mr. Gray's. He now says that it was anticipated by a paper of his, dated May 1880. He did not suggest this at the time; and, on reading the paper now, I can find no trace of the alleged anticipation. In the passage quoted above, and in other writings ("Earthquake Measurement," p 48; NATURE, vol. xxx. p. 152; "Encyclopædia Britannica," Art. "Seismometer"), I have tried to do justice to Mr. Gray's priority in the solution of this problem of vertical astatic suspension; but I prefer, and use, my own later solution.

J. A. EWING

University College, Dundee, December 11

How to make Colourless Specimens of Plants to be preserved in Alcohol

IN your last number (p. 149) Prof. H. de Vries described a valuable method for making botanical museum specimens colourless; but, as it is more important in many cases to keep the original colour, you will allow me to call your attention to a note in the *Berichte der deutschen botanischen Gesellschaft* (1886, No. 8), where Dr. Tschirch describes a method for retaining the colour (green or other) on specimens preserved in spirit. He discovered some time ago that tannates and colouring-matters (as found in plants), with the exception of xanthophyll, form compounds with lead and barium which are insoluble in alcohol, and he based his method on this discovery. He recommends the specimens to be put into solutions of compounds of lead or barium before transferring them to spirit, or simply to add concentrated solutions of acetate or nitrate of lead, or chloride or hydrated oxide of barium, to the spirit. I may add that I have tried this method, but I have not yet got quite satisfactory results. My best results were obtained by plunging the specimens first of all into boiling water before putting them into the above-mentioned mineral solutions.

SELMAR SCHÖNLAND

Botanic Garden, Oxford, December 18

The Recent Weather

MY barometer, at 250 feet above sea-level, fell to 28·20 at 5 a.m. on December 8, and to 27·82 at 8 p.m.

Birstal Hill, Leicester, December 18 F. T. MOTT

I GATHER from your notice of the great storm on the 8th that readings of the barometer taken during its passage across the country will be of some interest. I therefore place at your disposal copies of the records made at Belvoir Castle. An indication of an approaching storm was given by a falling barometer on the 6th, its reading at 9 a.m. on that day being 29·380. The depression increased on the 7th, reaching 28·960; at 9 a.m. on the 8th it had fallen to 28·200, and then went down rapidly, until at 9 p.m. it reached its lowest point, 27·800, the lowest I have registered at this place during a period of thirty-two years. During the 8th the wind was strong from the south, amounting to a gale, and was accompanied with rain, 0·60 being recorded, but it was less violent than the indications of the barometer led me to expect. That the pressure was less intense here than in the storm on October 14, 1881, was evidenced by the escape of timber-trees; some 400 to 500 were blown down in 1881, and not half a dozen in the woods adjacent to the Castle on the 8th. Belvoir Castle is in the northern division of Lincolnshire, about twenty miles east of Nottingham. The height of our station, but not of the Castle, is 237 feet, lat. 52° 53′ 39″·9 N., long. 0° 3′ 7″·4 W.

WILLIAM INGRAM

Belvoir

Electrical Phenomenon

I BEG to inclose extract from a letter just received from a young friend at Yloilo, and shall be glad if you will insert it in your next issue. Some of your readers may have further information respecting this interesting sight.

THOMAS HIGGIN

Ethersall, Roby, Liverpool, December 15

"*Yloilo, October* 1, 1886

"Last night a most extraordinary phenomenon was visible in the heavens. About 9 o'clock the sky was perfectly clear, all the stars visible, but no moon, when suddenly the whole heavens were lit up as if by electric light, a very large globe of fire became visible (about the size the moon appears when full) and floated slowly northwards. I was in rather a bad position for seeing where it actually went, a house being between me and the horizon. This ball was followed by smaller ones, which were close to the big one, and gradually got smaller, till they appeared like falling stars, only they went much more slowly."

Electricity and Clocks

WOULD any of your readers aid me in carrying out this idea: To make the works of a small striking clock strike the hours on a large bell by an electrical connection.

T. WILSON

Rivers Lodge, Harpenden, St. Albans

BOTANY OF THE AFGHAN DELIMITATION COMMISSION

WHEN, in 1884, it became known that the Government intended sending a Commission to settle the boundary of North-Western Afghanistan, representations were made to the Marquis of Ripon, then Viceroy of India, that it was desirable in the interests of science and commerce that a naturalist should be attached to the staff, and Brigade-Surgeon Aitchison was accordingly appointed in that capacity. Certainly no better choice could have been made, at least as far as botany was concerned, because no other person had the practical knowledge of the vegetation of the region possessed by Dr. Aitchison, who, moreover, is unsurpassed as a collector. As long ago as 1859 he began collecting plants in the Punjab, the flora of which he fully investigated; and later he collected in Scinde and some parts of Kashmir; but this was all done during his leisure hours. In the winter of 1878 he accompanied the troops under the command of General Sir F. Roberts in the advance on Kuram, and subsequently he was attached to the force as botanist, and commenced operations in April 1879. Botanists of all countries know full well what excellent and extensive collections he made during that and the following year, for, with assistance from the Government of India, the results were promptly published by the Linnean Society. Large and interesting as those collections were, the present equals them in extent and exceeds them in importance, inasmuch as Dr. Aitchison paid special attention to the investigation of the many vegetable products of the Perso-Afghan region which are articles of commerce with India and other countries. Much uncertainty existed respecting the plants yielding some of these drugs, dyes, and other substances, and no more welcome contribution to botanical knowledge could be made than the removal of this uncertainty.

The Commission left Quettah in September 1884, taking a south-westerly direction as far as Nushki, and thence the course was north-westward across Northern Baluchistan to the Helmund River, which was touched in about 63° E. long. This section of the journey produced little, as the country is very barren and the season in which it was traversed the worst of the year for botanising. Nevertheless a few interesting things were picked up, notably ripe fruit and seeds of *Stocksia brahuica*, which were previously unknown. The fruit, or seed-vessel, is an inflated capsule, similar to that of the Chinese *Koelreuteria*, near which *Stocksia* is placed, and so brightly coloured that it bears a name equivalent to "mountain peach."

That part of the journey from the Helmund northward to Kuhsan, a little to the north-west of Herat, was accomplished at the rate of twenty miles a day, therefore there was little opportunity for collecting. Indeed the fatigue attending the travelling was so great that frequent dismounting to secure specimens of natural history was out of the question. In spite, however, of all drawbacks and difficulties, specimens of about one hundred species of plants were dried; and this collection was despatched to India, by way of Herat and Candahar, where it arrived in a rotten condition, having apparently been immersed, probably in crossing some stream, during the transit. The small collection made in Baluchistan had in the meantime reached Kew safely.

The main collection of dried plants, consisting of about 800 species in 10,000 specimens, was made in an irregular tract of country lying between about 59° and 64° of longitude and 34° and 37° of latitude, with Herat near the south-eastern, and Meshed near the north-western limits. This collection was the result of one year's work; yet it by no means represents the entire flora of the area in question, partly in consequence of the difficulties attending the daily transport of collections constantly increasing in weight and size, and partly on account of the necessity for keeping with the main party. These contingencies, rather than the resources of the country, determined the extent of the collection. Thus, for instance, Dr. Aitchison rarely reached an altitude of more than 5000 feet, so that he collected no portion of the vegetation of the upper zone of the country. However, as the mountain flora is of more purely botanical interest, while that of the plains is of special commercial importance, on account of the number of economic plants it contains, its absence is, from the economic point of view, the less to be regretted.

At present the collection has not been fully worked out; but it is estimated that it comprises about a hundred species previously unknown to science, besides largely supplementing the material in herbaria of many obscure plants. Its principal value, however, as already mentioned, lies in the number of usually very complete specimens of economic plants and their products.

Foremost in importance, and the characteristic and dominating feature of the vegetation of the plains, are the *Umbelliferæ*. Some of these are of gigantic size, for herbs, and several of them yield valuable gum-resins, known in commerce as gum ammoniacum, gum galbanum, asafœtida, &c. A special paper on these plants was read by Dr. Aitchison on December 8 before the Pharmaceutical Society, therefore it would be superfluous to enter into details here. Early next year will be published a full and illustrated Report on the whole collection, in which prominence will be given to the economic plants: such as have not previously been figured, or only inadequately figured, will be selected for illustration. Remarkable among the *Umbelliferæ* not known to yield gum-resins are *Ferula oopoda*, Boissier, *F. suaveolens*, Aitchison and Hemsley, and *Dorema serrulatum*, Aitchison and Hemsley. The first we have identified with a described species, though the specimens are very fragmentary, and the description incomplete. It is a most singular plant, in which the bases of the cauline leaves are developed into large circular bowls, through a succession of which, gradually smaller upwards, the stem passes. The largest of these bowls are as much as a foot in diameter, and about two quarts in capacity. From his investigations on the spot, Dr. Aitchison is of opinion that these bowl-like expansions of the petioles do not serve the plant as reservoirs of water: possibly they may prevent the ascent of insects which infest and consume the fruit of many of the Umbelliferæ of the region. *F. suaveolens* furnishes a kind of sambal, and the *Dorema* is a very distinct new one. These *Umbelliferæ* form very beautiful miniature forests; *D. glabrum* growing as much as 10 or 12 feet high.

Among other economic products whose sources have been traced and good specimens of the plants secured, a yellow dye, largely imported into India, may be mentioned. It is furnished by an apparently undescribed species of *Delphinium*. Another dyeing material turns out to be the roots of a species of *Prunus* (*P.* (*Cerasus*) *calycosus*, Aitchison and Hemsley), remarkable in being apetalous; the petals being replaced by the coloured petal-like calyx-lobes. *Pistacia vera* Dr. Aitchison regards as undoubtedly indigenous in this region, and numerous other interesting facts of the same nature will be described in his Report.

In conclusion, it may be mentioned that Dr. Aitchison succeeded in bringing home his extensive botanical and zoological collections by way of the Caspian and Black Seas, in an admirable state of preservation. Of course, it will be understood that there is no difficulty in drying plants in Afghanistan and Persia. In fact, they are likely to get too dry, and consequently break and crumble to pieces in transport, especially when, as in this case, they are carried on camels and mules day after day; and it was only by the most careful and elaborate packing that the plants were prevented from being rubbed into powder.

W. BOTTING HEMSLEY

DEPOSITS OF VOLCANIC DUST

IN several recently-published papers,[1] Prof. George P Merrill has called attention to some interesting deposits which are shown by careful microscopic study to consist of volcanic dust.

Samples sent by Mr. Zahn, of Nebraska, to the United States National Museum were supposed to be "geyserite," and similar materials are said to occur in Western Kansas, Eastern Colorado, and Wyoming. They were found in small patches or in beds up to four feet in thickness, covered by a considerable thickness of other deposits. Of this material Prof. Merrill writes as follows:—

"A glance at the samples was sufficient to convince the writer that they were not the result of geyser action, but were probably of volcanic origin. One was of almost chalky whiteness, very finely pulverised, and of a sharp, gritty feeling when rubbed between the fingers. The second was gray in colour, slightly coarser, and had, even to the naked eye, a flaky appearance. Submitted to microscopic examination, both samples were found to consist almost entirely of the minute particles of amorphous glass, such as originate from the fine pulverisation of a glassy pumice, with only occasionally a fragment of a greenish mineral that was apparently hornblende."

[1] "On Volcanic Dust from South-Eastern Nebraska" (*Proc. Nat. Mus.* vol. viii. 1885, p. 99; "Notes on the Composition of Certain 'Pliocene Sandstones' from Montana and Idaho" (*Am. Journ. Sci.* vol. xxxii. 1886, p. 199).

The figures given of these particles show that they closely resemble pumiceous dusts (see NATURE, vol. xxix. p. 587). An examination of the sandstones with which these dusts are sometimes found interstratified proved that they consist of well-rounded particles of triclinic feldspar, hornblende, and magnetite, and that they are therefore, like the associated dust deposits, of volcanic origin.

Among a series of so-called "Pliocene sandstones" collected in Montana and Idaho in 1871 by Dr. A. C. Peale, of the Hayden Survey, Prof. Merrill was able to detect similar pumiceous sands in a more or less pure state. In their microscopic characters several of these were found to be very similar to the pumice-dust which was thrown out so abundantly during the great eruption of Krakatão.

"All of the above-mentioned dusts yielded water when heated in a closed tube, and fused readily, with swelling, before the blow-pipe. Samples submitted to Mr. J. E. Whitfield, of the Geological Survey, for analysis, yielded results as follows :—

	Marsh Creek Valley, Idaho	Little Sage Creek Mountain	Devil's Pathway
Ignition	6·00	6·50	5·60
Water [1]	1·60	1·12	3·46
$Fe_2O_3 + Al_2O_3$	16·22	18·24	17·18
SiO_2	68·92	65·56	65·76
CaO	1·62	2·58	2·30
MgO	trace	0·72	trace
Na_2O	1·56	2·08	2·22
K_2O	4·00	3·94	3·14
	99·92	100·74	99·66

Accepting the apparently well-founded conclusions of others to the effect that such dusts represent the extreme degrees of acidity of the lavas of which they formed a part, we are led to consider these as of andesitic or possibly trachytic derivation."

Other similar materials have been examined from Bridger Creek, on summit of a hill near Bozeman, and in connection with fossil bones from the Niobara Loup Fork and Sweetwater regions. A sample obtained from the base of the Mazatzol Mountains at the edge of Verde River Valley is stated to be quite similar to that described from the east of the Black Hills of Dakota, described by Dr. Wadsworth,[2] and also to those previously described by Prof. Merrill from Nebraska. Other similar dusts have been obtained by the officers of the United States Geological Survey from Wray Station in Eastern Colorado, and from Norton and Phillips Counties, Kansas.

"In studying the probable origin or sources of these various beds, the distances which the dust can be carried by atmospheric currents is likely to prove of importance. It may therefore not be out of place to state here, that among a collection of pumices, ashes, &c., from the Krakatão eruption in 1883, and which were donated to the Museum by T. H. Houghton, was a small sample of the dust (36974) that 'showered on board ship *Beaconsfield* at the rate of one inch per hour for three days, in latitude 14° S., longitude 92° E., or at a distance of 855 miles from the scene' of volcanic activity. This dust is a very pure, nearly colourless, gray and highly pumiceous glass, the particles of which vary in size all the way up to 0·25 mm.

"As a matter of economic interest I may say in conclusion that in Kansas and Nebraska these dusts are collected and sold in paper packages as 'diamond polishing-powder,' or put into soap which is sold for general scouring as well as for dental use under the name of 'Geyserite soap.'"

[1] Water given off at 105° C.
[2] *Science*, July 24, 1885.

THE POTATO TERCENTENARY

An article on "The Origin of our Potato," which appeared in our columns on May 6, contained these words : "It would be a fitting observance of the third centenary . . . if we could celebrate it, not by speeches and after-dinner toasts to the memory of Drake or of Ralegh, but by clearly laying down our lines of inquiry, for they have been very ill-defined." These words, penned by our contributor with then no definite idea as to the way in which various thinkers could be brought together to help to lay down lines of inquiry, have had their effect. The proprietors of the St. Stephen's Hall took the subject up, and in a circular headed 1586-1886, printed in old English type, referred to the article in NATURE as drawing attention to the fact that 1886 was the accepted date for the tercentenary, and announcing their intention to celebrate it in the spirit suggested, with Conferences and an historic and scientific Exhibition, conjoined with a display of all known varieties of tubers that could be obtained. A "Scientific Committee of Consultation" readily offered their services to arrange the "historic and scientific" portions of the Exhibition and to conduct the Conferences. Leaving, as it was seen we were, the old lines of cultivation, and entering on a more thoughtful, a more scientific way of procedure, the turning-point appeared to demand a recognition of the past, an exposition of present knowledge, and something tangible of the on-look into the future.

The proprietors of the St. Stephen's Hall, while acting as the executive, and arranging the display of tubers, and offering gold, silver, and bronze medals, left all the scientific work to the Committee of Consultation. Those who first accepted their responsibilities had to seek the co-operation of others, and only those who were specialists in the portion of the subject they represented were invited to join it. In the list of sections as drawn up, the botanical aspects of the question naturally came first, and Mr. J. G Baker, F.R.S., of Kew, undertook to illustrate "The Known Wild Species of Solanum," which he did partly by dried specimens and partly by drawings. No one was found to undertake the section "Batatas, yams, ighnamas, &c., that in Elizabethan times were called potatoes," but specimens of yams and so-called batatas were shown. Some uncertainty about the vernacular nomenclature of these seems to exist. The section "Cultivation by the Incas and other Andean Nations" was accepted by Mr. C. R. Markham, C.B., F.R.S., who in the Conference added more information than could be given in the form of an exhibit. For the next section on the programme, "Early Cultivation in the British Isles," no one could be found. This is a fact worth notice. There must surely be some one who has paid attention to this subject, yet even after the Committee was fully formed it was not known to whom to apply for information.

The next section, "Cultivation," with its sub-sections —(1) Selection, (2) Cross-breeding, (3) Hybridisation, (4) Grafting—was undertaken by Dr. Maxwell Masters, F.R.S.; and the following section, "Potato-disease," was well filled up with contributions from Mr. W. Carruthers, P.L.S., Mr. Worthington Smith, Dr. Plowright and Mr. Geo. Murray, F.L.S. For the section "Chemistry of the potato and batata as a food" Prof. Church sent new analyses, and Mr. W. Topley, F.G.S., of the Survey, contributed maps and notes on "Soils suitable for Potatoes geologically considered."

In "Meteorology as affecting Disease," Mr. J. G. Symons, F.R.S., exhibited rainfall maps showing coincidence with special disease years. The next section, "Historic literature of the potato," was in charge of Mr. W. S. Mitchell, M.A., and by the help of dealers in old books, and of private collectors, the list he had drawn up had but one gap—a Monardes. Such a collection has no before been brought together. The section "Maps show'ng the knowledge of the New World at the time of Elizabeth" was formed by the help of Mr. Coote, of the Map Department of the British Museum, Mr. C. R. Markham, Mr. Henry Stevens, and others. For the section "Ralegh" Dr. Brushfield, of Salterton, Devon, sent up his collection of works, which, with some additions, were arranged by Mr. H. B. Wheatley, F.S.A.; while the "Drake" section was mainly composed of an interesting series of illustrations sent up from Plymouth by Mr. W. H. K. Wright, of the Public Library. Mr. B. D. Jackson, Sec. L.S., contributed the works illustrating the "Gerard" section; but no one could be found to supply any information about Heriott, as that section was blank.

It is worth noting that this Exhibition was not one in which the list of sections followed what was sent in. What ought to be shown was drawn up first, and where the required works or maps, &c., could not be obtained the blank was understood.

Many unexpected curiosities arrived. Potatoes from Youghal, co. Cork, where it is said Ralegh planted his first potatoes in Ireland, were sent, together with views of his residence there where he conversed with Spenser. Irish cooking-pots of the same type as those in use 300 years ago, and rough garden, or possibly field, tools, were also sent over. Potato-culture in every aspect was represented, except in illustrations of the new methods of artificially fertilising by removing pollen from one flower to another.

As regards the show of tubers, the judges, Messrs. Shirley Hibberd, William Earley, and R. Dean, considered them well worthy of the occasion. The especial aim was that every known variety should be represented, and there was a special section for new varieties, introduced within the last two years, not yet in the market. The prize-winners of the medals offered by the executive have been made known in journals devoted to these subjects.

The Exhibition itself dealt with the past, including in that, history from the time of Ralegh and Drake down to the recent past,—Mr. Baker's work on distinct wild species of tuber-bearing Solanums, which he has reduced from six to four since his paper at the Linnean Society was read.

The chief scientific importance of the celebration of the tercentenary, however, lay in the Conferences.

At the opening, Mr. W. Carruthers, P.L.S., took the chair, and the first paper was read by Mr. W. Stephen Mitchell, M.A., on "Historic Consideration of the Question, whence came the Potato to England." Alluding to articles he had written, he said it was easy to see how the mistake had arisen that the introduction of the potato had been attributed to Ralegh, and that Virginia had been regarded as its original home; and he expressed his belief that Drake brought it from Carthagena in his 1586 expedition, on which expedition he had asked his friend, Mr. W. H. Pollock, to contribute a paper. This paper (read in the writer's absence by Sir Richard Pollock) detailed the expedition, and showed that there was opportunity for Drake to have taken on board the potato as ship's-provender at Carthagena. The supply at Carthagena depended on native cultivation. Then in due sequence followed Mr. Clements R. Markham's paper on "The Cultivation by the Incas and other Andean Nations." This paper proved to be the surprise for the Conference. The cultivation by the Incas was already fairly well known, as our article of May 6 showed, from the writings of Garcillasso de la Vega, Acosta, and Cieza de Leon. But the cultivation by the Chibchas was the revelation. Not only have the people died out, but their language has been lost. A *vocabulario*, however, has preserved many of the words they used, and nine varieties of potato are in it named. It is thus seen that before the Old-World people (the Spaniards) reached the New World, the potato had been so long cultivated, and that distinct varieties were recognised. Mr. Markham most eloquently described the high civilisation of the Incas, and with a large-scale lecture-map, belonging to the Royal Geographical Society, showed the regions of potato-cultivation as they can be inferred from early writers. Following most appropriately on this was Mr. J. G. Baker's paper on wild species of potatoes as known to botanists at the present day. In the discussion which followed, there was naturally raised the question, What are wild species, and what were cultivated by the Incas and other neighbouring peoples? but, of course, no definite answer could be given. This is one of our troubles. Mr. Markham's paper was also of very considerable interest. M. Henri de Vilmorin then gave a brief account of what he had been able to ascertain about the introduction of the potato into France, which he hopes to be able to work out more fully. This concluded the historic portion of the work of the Conference. Then Mr. George Murray, F.L.S., of the British Museum, gave an account of the history, of the study, and of the present state of our knowledge of the potato-disease. The facts he mentioned have already appeared in these columns. The day's work ended with a vote of thanks to the Chair, proposed by Earl Cathcart.

On the second day of the Conference, Mr. W. S. Mitchell in the chair, the first paper read was by Dr. Maxwell Masters, F.R.S., "On the Production of Varieties by Cultivation." It embodied the thoughtful appreciation of past work, and what has to be done in the future. It is on hybridisation our hope must mainly rest, on a cross by artificial fertilisation between two distinct species, all other "cultivation" being but a continued ringing of changes. It was, from a practical point of view, the most important communication made to the Conference. The following papers by Mr. W. Earley, Mr. A. Dean, and Mr. R. Dean took up the question of cultivation from the grower's point of view, and coming as they did from such recognised practical men they were of value. Mr. Hibberd criticised, from his own experiments, the value of the Jensen system of earthing-up, and stated his belief that it did not add to the crop, even if it might, as asserted, prevent disease from spreading. He suggested, and backed up his suggestions with reference to his own experience, that the early raising of a crop showing signs of disease was of use. The period for doing this, however, he did not mention, and to raise a crop before the starch is formed in the tubers would be of little real value. The suggestion, however, is one of importance for future consideration. He detailed an unintended experiment made during the last twelve months which is worth the attention of practical men. It will reach them through horticultural journals. Mr. R. Dean, in his paper, admitted that, although he had thought potato-culture was thoroughly "threshed out," he had come to see much remained to be done. The aim of the cultivator had been to produce handsome table tubers. Sufficient attention had not been paid to degeneracy and the causes of it. Again, though it is very well to produce new varieties, the trouble is to get them into general use. People will follow their old lines. In the course of his paper he advocated deep tilling. Mr. A. Dean, in reading on "Raising new varieties of potatoes," referred to the fact that some cultivated varieties do not produce any flowers, and some with flowers do not mature pollen. He detailed several experiments in crossing, and especially drew attention to varieties that do or do not produce much haulm. As it is through the leaves on the haulm that the disease reaches a plant, this is a matter of importance. In the course of the discussion Mr. Ap Thomas gave some valuable information about potatoes in South America, and Earl Cathcart expressed the hope that the information should be in some form preserved.

After the usual votes of thanks had been passed, the generally expressed opinion in conversation was that the Exhibition should have been open for four weeks instead of four days. That the Conferences, by bringing together people who view the whole subject from different standpoints, have done good appears to be admitted. The future will show.

NEW ZEALAND COLEOPTERA[1]

IN an important memoir quite recently published, Dr. Sharp describes a large number of new species of Coleoptera from New Zealand. Although the entomology of these islands is of considerable interest, it is still very imperfectly known, and a quite erroneous idea as to its poverty is very often found to exist. Linnæus knew of no Coleoptera from the group, but a small number had been obtained by the naturalists of Capt. Cook's voyage. Some of these were described by Fabricius about a century ago, and a few of these are still to be found in the Banksian Collection at South Kensington, but from Cook's day until the date when the island was visited by Her Majesty's ships *Erebus* and *Terror* little was done in the way of investigation. When Adam White published the account of the Coleoptera of this last Expedition (1846), he enumerated all the species of the group known to date to inhabit New Zealand, and the total was about 150; however, between 1866 and the present time, the greatly increased activity of collectors swelled the number of species known to nearly 1500, and in the memoir we are now noticing Dr. Sharp describes 141 additional forms. Dr. Sharp still, however, regards the Coleopterous fauna as very incomplete, and on the consideration of such data as he possesses ventures on an estimate that between 3000 and 3500 species will probably be found in New Zealand; so that there is an immense field still open for collectors. The fauna so far as known is very analogous to that of Europe in extent and complexness. The species when examined show similar structures, exhibiting analogous gradations and cross affinities, but the New Zealand insects possess a larger proportion of forms in which the structures are less perfect—comparatively, as it were, little evoluted. In brilliancy of colour and in large and conspicuous forms, the New Zealand Coleoptera are very deficient, but to the specialist they make up for this in the interest attaching to many of them as isolated forms having, so far as is at present known, little or no connection with the ordinary Coleopterous fauna of the island.

While the data are so imperfect it is obvious that no reliable answer can be given to the question of the affinities of the New Zealand fauna; but Dr. Sharp, from what is known, entertains the impression that it will be in the Chilian and Patagonian fauna that the greatest amount of affinity will be found, and that, while numerous points of propinquity with the Australian fauna undoubtedly exist, yet they are rather exceptions dealing with isolated forms, and but little affect the mass of the fauna.

Lasiorhynchus barbicornis is the only member of the Brenthidæ found in New Zealand, and is perhaps the most remarkable beetle of the islands; it must be considered a highly evoluted form, the sexual differentiation being great, with remarkable male characters, large size, and considerable perfection of general structure, and while it appears to be quite foreign to the New Zealand fauna, it would seem to have no really close ally in any other country.

Another isolated form, of large size, for many years known, but still a great rarity, is Dendroblax. Its position has never been satisfactorily fixed; it has no ally in New Zealand, and no near ally out of it. Such cases are extremely difficult to explain. Dr. Sharp thinks it possible that there has been going on in New Zealand, for an enormous period of time, the evolution of a fauna parallel with that of the continents of the world, and that during this period it has occasionally received intrusions from other countries, some of which have continued to evolute since their introduction, while others have remained with little change. On such a view Dendroblax might be an ancient intrusion into New Zealand, which has become extinct elsewhere, and has evoluted but little in New Zealand; while Lasiorhynchus might have evoluted much since its introduction.

This memoir forms a part of the *Scientific Transactions* of the Royal Dublin Society, and both as regards the paper and press-work it is extremely creditable to the Society. The two quarto plates contain fifty figures of the new species described. These are from the pencil of Baron Schlereth, of Vienna, and are among the best illustrations of Coleoptera we have seen. The plates have been printed after a new and brilliant process by Bannwarth, of Vienna.

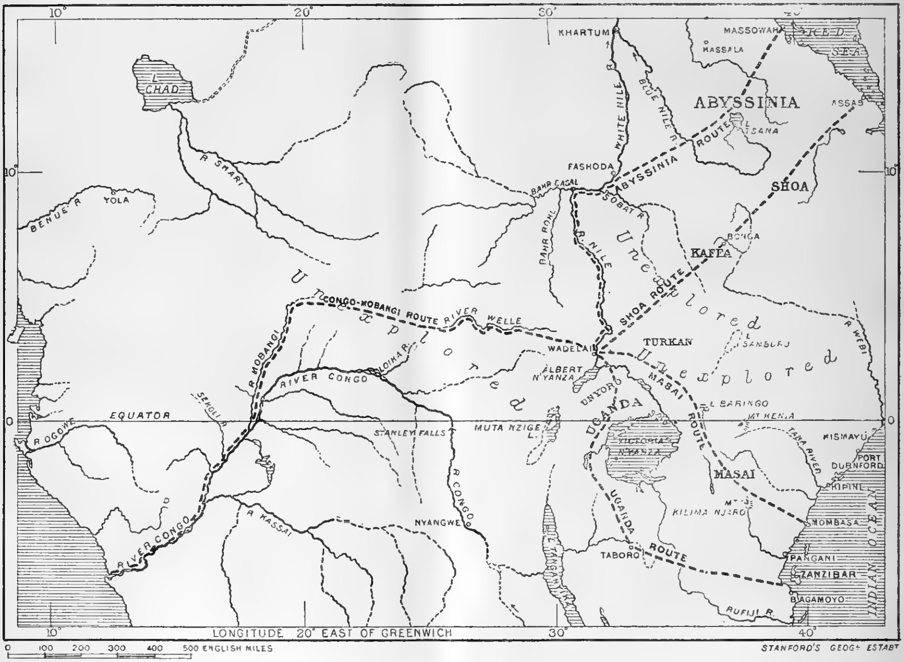
[1] "On New Zealand Coleoptera, with Descriptions of New Genera and Species." By David Sharp, M.B. With two plates. (Dublin, 1886.)

THE RELIEF OF EMIN PASHA

EVERYBODY seems agreed that Dr. Schnitzler, better known as Emin Bey, but recently created Emin Pasha, ought to be relieved; for he does not want to be rescued. For ten years he has been in the Egyptian service, for most of that time as Governor of the Equatorial Province, which, in spite of the Mahdi and his hordes, the death of Gordon, and the collapse of the Egyptian Soudan, he continues to administer with success, and to the comfort and satisfaction of all but slavers. What Emin Pasha has done for science in the little leisure left him by his arduous duties, the readers of *Petermann's Mitteilungen* and the *Proceedings* of the Zoological Society know. He is a good type of the kind of explorer that is wanted now that mere pioneering work has been pretty well exhausted: a man well qualified by his scientific training to remain in a particular region for years if necessary, and study it in all its aspects. We have had such men in the past: some of the greatest names in science could be mentioned as examples. We do not insist in these pages on the great services which Emin Pasha has rendered to civilisation during his residence in the Soudan, first as the noble-minded Gordon's lieutenant, and latterly as one who, in the spirit of Gordon, resolved to stick to what he conceived to be the post of duty at all hazards. Our own Government has virtually admitted its responsibility for the present position of Emin Pasha, but has weakly attempted to shirk its duty by devolving the business of relief on private individuals. Should disaster happen, however, to Emin Pasha or to any expedition sent to his relief, we may be sure that public opinion will not blame any private individuals. Government, however, has gone so far as to promise every assistance short of contributing money.

It is unfortunate that already there has been a delay of several months since first we knew of Emin Pasha's critical position, and since first the Intelligence Department began to make inquiries as to the best route for a relief expedition. Even now, when an expedition has been decided upon, there seems little prospect of a speedy start. Surely, if those to whose hands the 10,000*l*. contributed by the Egyptian Government have been intrusted had the interests of Emin Pasha solely at heart, a competent leader would have by this time been within hail of Zanzibar. A better leader, under the conditions, than Mr. Stanley could probably not be found; but surely there has been unnecessary delay in deciding to send him. The idea of more than one expedition is entertained by many; and, as our map will show, the most direct and safest route is by Masai Land, about which we now know so much through the journeys of Mr. Thomson and the late Dr. Fischer. Dr. Junker telegraphs from Zanzibar that a relief expedition is urgently necessary, and that as fighting is inevitable, Mr. Stanley ought to be sent. By the Masai Land route, as shown on the map, avoiding Unyoro and Uganda, and skirting Lake Baringo and Turkan, we doubt if any fighting would be necessary. We have reason to believe that the King of the Belgians will not object to Mr. Stanley undertaking an expedition, and that Mr. Stanley will choose the East Coast route, but whether through Masai Land, or by the the west side of Lake Victoria Nyanza, and so on to Albert Nyanza, remains to be seen. What geographers would like most of all, would be an expedition by the Congo and Mobangi Rivers. In this way, not only would fresh discoveries be combined with the relief of Emin Pasha, but, by sending out two independent expeditions, the latter would almost certainly be accomplished.

Our map is intended to show the various routes that have been proposed. There is, first, the Masai Land route described above, the total length of which, to Wadelai, where Emin Pasha is stationed, is only 820 miles, and thus is the shortest of all the routes. Mr. Thomson has traversed this route to within 300 miles of Wadelai, and these 300 miles are as yet unexplored. The most formidable difficulty here would be the bellicose Masai, but these, Mr. Thomson has shown, can, after all, be managed. By keeping well to the east, there would be little danger of the cruel young potentate of Uganda hearing of the expedition, and so the lives of missionaries and native Christians would not be endangered. Next is the Uganda route, which is understood to be favoured by Mr. Stanley, and which is 1050 miles in length, and all previously traversed. Most tempting of all the routes, if exploration were the only object in view, would be the Congo-Mobangi route. The Mobangi is one of the greatest of the tributaries of the Congo, and



STANFORD'S GEOGL. ESTABT

has been navigated for about 250 miles by Mr. Grenfell. On the other hand, Dr. Junker has been down the Welle-Makua to 22° E., within about 200 miles of Grenfell's farthest. Now, if we were certain that the two rivers were one, in spite of the rapids on the Makua this is a route we should be strongly inclined to support. But no risks should be run and no experiments tried in a matter so critical. By all means send an expedition by this route, and solve one of the few remaining hydrographical problems in African geography. We must say, however, that those best acquainted with the levels in this region still maintain that the Welle does not come down to the Congo at all, or, if it does, not by the Mobangi. This route is 1900 miles in length. The Abyssinian route, in our opinion, does not deserve any consideration so far as the relief of Emin Pasha is concerned, though there is some exploring work to be done in this direction. The total length from Massowah to Wadelai is 1400 miles,—Massowah to Fashoda 700 miles, of which at least one half is unexplored, and from Fashoda to Wadelai by the Nile about 700 miles. In the same category as the Abyssinian route is the Shoa route—1050 miles, from Assab to Wadelai, 300 miles being unexplored. There is also a rumour that the King of the Belgians intends to send Mr. Stanley up the Nile, but this is a rumour that can scarcely be credited.

Altogether it seems evident that, if Emin Pasha is to be reached with the least possible delay and with substantial relief, the Masai Land route is the one to take. There is one important consideration that must be mentioned. With a caravan consisting solely of men they could take only what they themselves would consume, and it is difficult to see how a supply of ammunition and other necessaries could be conveyed. Now, by Masai Land it is all but certain that camels could be utilised, and these animals could find their own provender. With 30 or 40 camels and 60 donkeys, very substantial relief could be taken to Emin Pasha. Indeed, the whole route, at least to the borders of Emin Pasha's province, is so comparatively level that Cape wagons could be taken, though in such an expedition it would not be advisable to try the experiment. The important thing is that there should be no further delay in starting at least one expedition, whoever the leader is to be.

Mr. Stanley was to arrive at Southampton yesterday, and we may be sure that if there is any delay in getting an expedition under way he will not be to blame.

NOTES

On the 15th inst. a meeting was held of the Association for Promoting a Teaching University for London, when the Committee presented their second report. At a meeting held in December 1885, the Committee were instructed to open communications with the governing bodies of the University of London, University College, King's College, the Royal College of Physicians of London, the Royal College of Surgeons of England, and the various Medical Schools of London, as well as with the Council of Legal Education, for the purpose of promoting the objects of the Association on the basis of that report. The Committee have been informed by the Senate of the University of London and by the Councils of University College and King's College, that committees of those bodies had been appointed to consider the objects and proposals of the Association. The Council of King's College have adopted a resolution to the effect that "the Council, while reserving their opinion as to the details of the scheme laid before them by your Committee, approve generally of the objects which the Association has in view." The subject having been brought before the Council of University College, they adopted a resolution to the following effect:—"That this Council do express a general approval of the objects of the Association, which are as follows:—(1) The organisation of University teaching in and for London, in the form of a teaching University, with Faculties of Arts, Science, Medicine, and Laws; (2) the association of University examination with University teaching, and direction of both by the same authorities; (3) the conferring of a substantive voice in the government of the University upon those engaged in the work of University teaching and examination; (4) existing institutions in London, of University rank, not to be abolished or ignored, but to be taken as the bases or component parts of the University, and either partially or completely incorporated, with the minimum of internal change; (5) an alliance to be established between the University and the Professional Corporations, the Council of Legal Education as representing the Inns of Court, and the Royal Colleges of Physicians and of Surgeons of London." A conference between the deputation of the Committee named in that behalf and the Committee of the Senate of the University of London was held on November 23 at the University of London; and, at the conclusion of a long and important discussion, the Vice-Chancellor gave to the deputation the assurance that the general disposition of those present was to move in the direction indicated by the Association. Various other institutions have virtually expressed approval of the object of the Association, and, while awaiting some further communication from the Senate of the University of London, which it is understood will be made, either to them, or in an independent way to the University teachers of London, the Committee propose to take steps for bringing to the notice of Her Majesty's Government the need which exists for the co-operation of the Government and of the Legislature, in order to place University teaching in London on a more satisfactory basis.

In connection with the report referred to above, the *University College Gazette* of December 17 contains a long article sketching briefly the career of University College, and alluding specially to the results of its severance from the University. The University, the article maintains, has carried out with great success, and to the great benefit of many workers, its design of a testing machinery that should enable it to throw its degrees open to all the world, without restrictions of any sort. It has grown to be a great Imperial University. Whatever faults there may be in its imperial system are of a kind to be corrected in the ordinary course of administration as time proves the need. On the side of the University of London, there is leisure now to go back to the point of separation from the Colleges, and having done one part of its work well, see that it does not leave the other undone. On the side of the Colleges, and of London itself, there is now a determination that the chief city of the world, abounding in the best elements of a true University life, shall not remain without a teaching University. The first aim of University College, the article goes on to say, is to form an alliance with the present University, by large expansion of its powers. "The desired work can be done so much more thoroughly by the University in concert with the College, and the issues are so important for their influence on the London of the future, that, if the result of the present deliberations at the London University were but faintly satisfactory, effort towards united action should be steadily continued by our College. Not until it has been proved (apart from rash assumption) that the desired concert cannot be obtained, should we consider that the time had come for advancing our next line of battle. Then it must be our resolve to apply all our powers to the creation of a separate teaching University in London; to the resuming of our first battle, and recovering for University College the position it gave up on conditions that are no longer fulfilled. King's College will join forces with us, but with or without allies we must press on to victory, and in this form of the battle, should we be forced to it, we depend on ourselves; we shall have public feeling with us, and the fault will be ours if we fail."

The death is announced, on Friday last, of Sir Douglas Forsyth, at the age of fifty-nine years. He will be best known to science as the leader of the mission to Kashgar, the report on which, only recently completed, forms so valuable a contribution to the natural history of Central Asia.

It is evident that at Rodriguez, a small dependency of Mauritius, the indigenous plants are threatened with extinction from an enemy of a peculiar character. In the Annual Report of the Acting Civil Commissioner on Crown Lands and Forests for 1885 it is stated:—"In my report for the year 1884, I pointed out the existence of a kind of white lice, commonly called here 'cochenille,' which had in a very short time multiplied enormously, and threatened to destroy the forests of Rodriguez. During the year 1885 matters looked more alarming still. It was reported to me that these insects had begun to attack the maize, manioc, and bean plantations: I myself while visiting the mountain ascertained the correctness of the report. However the bean harvest had not been bad, and the inhabitants had not to suffer from any scarcity of food. As regards the citron, lemon, and orange trees, for which this island has long been famous, hundreds of them have been killed by these insects. The mango and cocoanut trees felt their baneful influence, and yielded sour and unsavoury fruits. One of the best forest trees which grow here, the 'Bois puant' (*Fœtidia mauritiana*), seems unable to resist their attack, and I am afraid that there will not be one of these trees left within a twelvemonth, unless, by some happy circumstance, these insects were to disappear altogether." We learn from Kew that the interesting indigenous tree, whose complete extinction within twelve months is here anticipated, is very rare in Mauritius, and unless steps are taken to preserve it at Rodriguez, it will probably disappear altogether as a forest tree from the flora of these islands.

A MEETING of students anxious to form a Biological Society in connection with University College, London, was held on Monday, the 13th, in the Zoological Theatre, Prof. Lankester in the chair. The provisional Committee appointed at the first meeting submitted to the Society the rules they had drawn up, which after some discussion were passed with slight amendments, and sent up to the Council for approval. Many lady-students were present at this meeting, and so strong is the wish on all sides that they may be admitted to the Society, especially as the classes of Botany and Zoology have been thrown open to them, that two lady-students were put up as candidates for the Committee, and only missed election by a few votes.

AT a meeting of biologists held in the Natural History laboratory, University College, Liverpool, on Saturday, December 11, it was resolved to found a Biological Society in Liverpool, to have for its object the study and advancement of zoology, botany, palæontology, anatomy, physiology, and embryology, and the publication of papers of scientific value on any or all of these subjects. The following gentlemen were elected as office-bearers for the ensuing year:—President: Prof. W. Mitchell Banks, M.D., F.R.C.S.; Vice-Presidents: James Poole, J.P., Mayor of Liverpool, and Prof. W. A. Herdman, D.Sc., F.R.S.E.; Treasurer: J. C. Thompson, F.R.M.S.; Secretary: R. J. Harvey Gibson, M.A., F.R.S.E. It was decided to hold the first meeting of the Society at University College on Saturday, January 15, 1887, when the work of the Society will be initiated by the delivery of an inaugural address.

DURING a recent voyage of the U.S.S. *Juniata* to South America, observations were made as to the height and length of waves, with the following result, as reported by Commander Davis: height of wave from hollow to crest, 25 feet; length from crest to crest, 375 feet; wave-period, 7·5 seconds. The wind-velocity at the time was 10 miles per hour. The height of wave was measured by the elevation at which an observer could see over the crest when the ship was in the hollow. The wave-period was estimated by counting the average number of waves per minute. The wave-length was determined by the time occupied by the crest in passing a measured portion of the vessel's length.

IT is stated that the task of working up the materials collected by the survey parties of the Afghan Boundary Commission during the past two years into a regular series of maps has been undertaken by Capt. Gore, R.E., and that it will be carried out at Dehra Dun.

HIGHER mathematics in its applications to social problems is the subject dealt with in a new Vienna journal, *Die Controle*, which is edited by the mathematician, Dr. Grossmann. In an appendix, entitled "Die Mathematik im Dienste der National-œkonomie," questions of national economy are treated on a mathematical basis.

PROF. DEWAR'S course of six lectures on the Chemistry of Light and Photography (adapted to a juvenile auditory) which begin on Tuesday next (December 28) at the Royal Institution will be very fully illustrated. Arrangements have been made for the introduction of a powerful beam of electric light, equal in intensity to a sunbeam, into the theatre, for photographic experiments. Many improvements have been made in the warming, lighting, and ventilation of the theatre during the autumn recess.

THE last mail from Singapore brings news of the death there, on November 29, of Mr. William Cameron, explorer and geologist to the Government of the Straits Settlements, at the age of fifty-three. Mr. Cameron, after an eventful life in England and Australia, settled down in the Straits Settlements, where his practical knowledge of mineralogy and geology, combined with his love of exploration, procured him several appointments. Lately he had been employed by the Colonial Government in exploring and mapping out the unknown parts of the Native States, and he received the title of Government Explorer and Geologist. The production of one of his maps of these States has recently been noticed in these columns. He was well known throughout the Native States, especially amongst the Malays and Sakies, of whose language and customs he is said to have had a most accurate knowledge, and over whom he had great influence.

ON December 18 the fine new Ethnological Museum at Berlin was ceremoniously opened by the Crown Prince, who was accompanied by the Princess. The Museum, which is a very fine large building, contains collections from all parts of the world, including the antiquities dug up by Dr. Schliemann at Ilion. Herr Gossler, the Minister of Public Worship, read an address on the nature and objects of the institution, and the Crown Prince in replying referred among other things to the benefits which had accrued to the Museum from the colonial expansion of the Empire.

AT the last meeting of the Paris Geographical Society, M. de Lesseps was in the chair. After having heard an account of an exploration in the Panama Isthmus by M. Désiré Charnay, the Chairman spoke about the canal. He said that, if necessary, sluices should be constructed, so that the canal should be opened at any price in 1889. Ulterior steps should be taken for dispensing with them.

WE have received the report of the Leicester Literary and Philosophical Society for the past year, and also the first number of the new quarterly series of the *Transactions*. The reports from the various sections contained in the former are in all respects but one eminently satisfactory, as they show great activity and excellent work. The exception is Section B, for astronomy, physics, and chemistry, in respect to which it is stated that there is "a lack of interest in Leicester in physical science, especially when real work is to be done." Indeed, it has become a question whether the Council should not be asked to terminate the existence of the section; but "the Council express a hope that the section may live through its time of depression, and, when the interest in physical science has revived, may regain its vigour." We are glad to observe that the botanical sub-committee, who have undertaken and are now editing a work on the flora of Leicestershire, have nearly completed the printing of the book, and hope to be able shortly to announce its publication. The *Transactions* will in future be published quarterly, in place of annually with the Council's report. Of the first quarterly number of the *Transactions* little need be said. It speaks well for the prosperity of the Society that the annual publication no longer supplies its requirements, and the high standard of the papers read is shown by the fact that a number of them have been published by scientific periodicals of repute. The papers now published deal mainly with scientific subjects connected with Leicestershire, such as the Campanulas of that county, the Lower Lias and Rhætics in the Spinney Hills, Leicester, &c. Special mention should be made of a very interesting chart by Mr. Montagu Browne, giving the dates of arrival of summer birds of passage in Leicestershire, from 1843 to 1855, and from 1877 to 1886.

WE understand that Mr. H. S. Vines is intending entirely to re-cast and almost re-write his edition of Prof. Prantl's "Elementary Text-Book of Botany," and that his new work may be expected from Messrs. Swan Sonnenschein and Co. in the ourse of next year. In the meantime the publishers are reissuing the existing book without alteration.

IN the annual report of the Leyden Museum for the year ending September 1, 1886, Dr. Jentink, the Director of the Museum and the successor of Prof. Schlegel, is able to report substantial progress with the zoological collections, the most noticeable additions being an egg of *Æpyornis maximus* and a skeleton of *Echidna bruijnii*. Considerable series of animals of all classes have been added to the Museum from the travels of Mr. Stampfli in Liberia and Mr. Van der Kellen in Benguela.

ACCORDING to the *Colonies and India*, the last experiment in sending salmon-ova to the antipodes appears to have been a great success. In January 1885, a shipment of eggs was made by Mr. James Youl, by desire of the Tasmanian Government, and the bulk of the eggs reached the colony in good condition, development of the embryo having been suspended by means of Haslam's refrigerating machinery. The eggs have developed into "fry," and the "fry" into "smolts," for several young salmon about 8 inches long have been captured accidentally in the Tasmanian Mersey.

THE same journal states that a Mining Institute has been successfully launched at Sydney, with a programme of future work calculated to increase the welfare of the mining industry.

IN the Reingraben slate of Polzberg, near Lunz (Austria), among other fossils a well-preserved skull of Ceratodus has been found. Two years ago a flat-pressed vertebral column was found in the same place, which seems to have belonged to the same animal.

THE additions to the Zoological Society's Gardens during the past week include a Red-handed Tamarin (*Midas rufimanus* ♀) from Surinam, a Mauge's Dasyure (*Dasyurus maugæi*) from Australia, presented by Mr. Robert J. Hamilton; two Collared Peccaries (*Dicotyles tajaçu*) from South America, presented by Mr. Thomas Bell; two Peafowls (*Pavo cristatus* ♂ ♀) from India, presented by Mr. Richard Hunter; two Indian Crows (*Corvus splendens*) from India, presented by Lord Lilford, F.Z.S.; a Yarrell's Curassow (*Crax carunculata*) from South-East Brazil, a Razor-billed Curassow (*Mitua tuberosa*) from Guiana, a Red-billed Tree Duck (*Dendrocygna autumnalis*) from America, two White-faced Tree Ducks (*Dendrocygna viduata*) from Brazil, presented by the Rev. W. Bramley Moore; four Herring Gulls (*Larus argentatus*), British, presented by Capt. S. T. Sargent; six Spectacled Salamanders (*Salamandrina perspicillata*) from Italy, presented by Prof. H. H. Giglioli, C.M.Z.S.; a Macaque Monkey (*Macacus cynomolgus*), an Isabelline Bear (*Ursus isabellinus* ♂) from India, deposited.

OUR ASTRONOMICAL COLUMN

BARNARD'S COMET.—This comet has become an exceedingly interesting object, of no small beauty and brightness. Prof. Cacciatore, Director of the Palermo Observatory, in a letter appearing in the *Giornale di Sicilia* of December 1, speaks of it as visible to the naked eye. He says:—"Its head shines as a star of the fifth magnitude, and is accompanied by two tails, the one directed to the north-west, of a length of about a degree and a half, and the other to the west, about half a degree in length." But few observations would seem to have been made of the comet in this country, when the comparative brilliancy of the object is borne in mind; still, several English observers have called attention to the second tail. One observer speaks of the brighter tail as being, on December 9, more than 10° in length, and visible to the naked eye; the second tail, which was inclined at an angle of 40° to the other, was much fainter and shorter, and required an aperture of about 2 inches to show it well. The comet is now receding rapidly both from the earth and sun, and as its declination is diminishing, it will soon be lost to English observers.

ROTATION-TIME OF THE RED SPOT ON JUPITER.—Prof. Young, in the December number of the *Sidereal Messenger*, gives a fresh determination of the rotation-period of the great red spot on Jupiter. The determination rests upon eight observations made in the spring of the present year, and the rotation-period deduced is 9h. 55m. 40·7s. ± 0·2s.; the probable error of a single observation being ± 44s. This rotation-period shows that the gradual retardation of the period still persists, the following having been the values deduced in former years:—

			h. m. s.
In 1879	Mr. Pratt made the period		9 55 34·9
1880–81	Mr. Hough	,,	37·2
1882–83	,,	,,	38·4
1883–84	,,	,,	38·5
1884–85	,,	,,	40·1

Prof. Young remarked the apparent overlapping of the southern belt and the red spot which took place towards the end of March and the beginning of April, and which was observed by many English observers (*Observatory*, May 1886, p. 188); but, whilst admitting that it was impossible to say which was uppermost, Prof. Young was inclined, in opposition to Mr. Denning's view, to believe the red spot to be the lower. Mr. Denning has pointed out that the apparent partial coalescence of the two markings was simply due to an arm of the southern belt overtaking the red spot, the former having a rotation-period shorter by about 19s. than the latter. Prof. Young observed a white spot in a yet higher latitude than this part of the southern belt, and deduced a period of rotation for it of 9h. 55m. 11·14s. It would thus appear that the red spot moves more slowly than the markings on either side of it, to the south as well as to the north.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 DECEMBER 26—1887 JANUARY 1

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on December 26

Sun rises, 8h. 7m.; souths, 12h. 0m. 51·4s.; sets, 15h. 54m.; decl. on meridian, 23° 22′ S.: Sidereal Time at Sunset, 22h. 14m.

Moon (one day after New) rises, 8h. 32m.; souths, 12h. 56m.; sets, 17h. 22m.; decl. on meridian, 18° 54′ S.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	6 18	10 28	14 38	20 50 S.
Venus	8 35	12 25	16 15	23 49 S.
Mars	9 47	13 57	18 7	20 55 S.
Jupiter	2 32	7 40	12 48	10 52 S.
Saturn	17 6*	1 10	9 14	21 44 N.

* Indicates that the rising is that of the preceding evening.

Variable Stars

Star	R.A. (1887·0) h. m.	Decl. (1887·0) ° ′		h. m.	
U Cephei	0 52·3	81 16 N.	Dec. 28,	0 24	*m*

GEOGRAPHICAL NOTES

SEVERAL recent German geographical periodicals refer to a paper read by Prof. Kan, of Amsterdam, before the Section for Geography and Ethnology at the fifty-ninth Congress of German Physicians and Men of Science at Berlin in September, urging on German explorers the necessity of undertaking a geographical and geological exploration of the Moluccas. He said that, although Europeans had settled in the islands for centuries, our knowledge of the orohydrography, especially of the physical features of the archipelago, was exceedingly small. Excellent charts exist in abundance, and travellers, English and German, have subsequently visited it; but they were neither geographers nor geologists, but as a rule studied only the fauna and flora. The Dutch Government has done nothing as yet in reference to the geography of the Moluccas, because it has turned all its energies to procuring good maps of the more extensive Sunda Archipelago. Java has been triangulated and surveyed; there are excellent charts of the coast of Sumatra, and the triangulation of this great island has also been commenced, and, in late years, maps of parts of Celebes and Borneo have been produced. In geology, those islands of the Sunda Archipelago which contain useful minerals have been studied, and excellent geological maps of Sumatra, Banka, Billiton, South-East and North-West Borneo have appeared. In addition, the Government places annually at the disposal of the Geographical Society of Amsterdam 10,000 florins, which, Prof. Kan hoped, would next year be applied to the exploration of the Aru Islands. On the whole, therefore, the Dutch authorities are not lax in surveying and mapping their possessions in the East. Besides the Moluccas, Flores and Timor still offer a virgin field to the explorer, and Prof. Kan hinted that the traveller who undertook the work would not lack pecuniary or other help in Holland.

THE last number of *Petermann's Mitteilungen* contains the conclusion of Lieut. von François's account of his journey in the Southern Congo basin, the present instalment being mainly occupied with climatology and detailed hydrographical observations. Dr. Philippi also concludes the very interesting paper, to which we have already referred, on the changes wrought by man in the flora of Chili. It contains systematic tables of the plants introduced into Chili, and which it now has in common with Europe. Dr. Emil Jung continues his examination of the last census returns of India, the special subject in this number being the effect of the last famine on the movement of the population. There is, further, a brief review of the new edition of Berghaus's "Physical Atlas," and notes on an excellent map of the Dobrudja, which is appended.

WE have also received the last supplementary number (No. 84) of the *Mitteilungen*. It deals with the economical geography of the whole of North America, and is really the first number of a series called *Archiv für Wistschaftsgeographie*. It treats of agriculture, forestry, mining, industry, trade, shipping, &c.

AT the last meeting of the Paris Geographical Society (November 19), M. Hansen-Blangsted read a communication on the physical appearance of Denmark in the middle of the eleventh century, as compared with the present time. M. Venukoff referred to the results of M. Nikolsky's studies last year of the physical geography of Asiatic Russia, especially the gradual drying up of Lake Balkash. The level of the lake is lowered by about 1 metre every fourteen or fifteen years. Two letters addressed to the Ministry of Public Instruction by M. Chaffanjon *en route* for the Upper Orinoco, were read, one from Ciudad Bolivar, the second, dated August 18, from Caicara. An interesting communication was read with regard to the last resting-place of Tavernier, the celebrated French traveller, who died in 1689. It was long unknown where he was buried, but it has at last been discovered to be the Protestant cemetery at Moscow. The question of the best method of permanently marking the grave was referred by the Society to a Committee. Capt. Longbois read a humorous account of a journey to Choa, which had for its object the exploration of the Awash and its basin.

THE current number of the *Boletin* of the Madrid Geographical Society contains an interesting account of Don Manuel Iradier's recent explorations in the newly-acquired Spanish territory on the west coast of Africa. The enterprising explorer paid two visits to this region—first in 1875-77, and again in 1884-85, during which he traversed 4000 miles between the equator and 3° N. lat., penetrating from the sea-board into the interior as far as about 20° E. long., and surveying to their sources all the coast streams between the Rio-del-Campo and the Gaboon. By far the largest of these rivers is the Muni, which enters the Atlantic in Corisco Bay, after receiving the contributions of the Utamboni, Noya, and other considerable affluents on both sides, and draining an area of nearly 6000 square miles between the Gaboon and the Rio San Benito. The whole of this river-basin is now Spanish territory, the protectorate having been everywhere accepted by the chiefs of the local tribes, who are collectively known as Vengas, and belong in type and speech to the Bantu family.

THE same *Boletin* reports the arrival in Lisbon of Major Serpa Pinto and Lieut. Augusto Cardoso, leaders of the Portuguese Expedition, which has just completed the exploration of the region between Mozambique and Lake Nyassa. Starting from Ibo, south of Cape Delgado, the explorers advanced to the Mutepuezi River, and thence to Medo, where, Serpa Pinto falling ill, Cardoso took the lead. After traversing the Metarica district, the Lienda, an affluent of the Rovuma, was followed for some days, and found not to rise in Lake Nmaramba, but to flow through that lacustrine basin from Mount Songe, further to the west. From this point Lake Nyassa was reached in the Ki-Rassia district, whence the explorers proceeded by the familiar route down the Shiré to the Zambesi, and so on to Quilimane, on the coast. Being provided with excellent instruments, the explorers were able to take a very large number of astronomical and meteorological observations in a region now for the first time systematically surveyed.

THE prospectus has been issued in Vienna of a new geographical periodical to be called *Geographische Abhandlungen*; the editor is Prof. Penck, of the Vienna University, and Herr Hölzel is the publisher. It is not intended to compete with any existing geographical publications, but rather to supplement them. Each number will be complete in itself; compilations will be wholly excluded, and although a certain number will appear in the course of a year, the dates will not be fixed beforehand, in order to leave the writers as unfettered as possible. The three numbers promised are on the glaciation of the Salzach district, the orometry of the Black Forest, and the arrangement or distribution of the Eastern Alps, by Drs. Brückner, Neumann, and Böhm respectively.

ON SOME FURTHER EVIDENCES OF GLACIATION IN THE AUSTRALIAN ALPS[1]

SINCE my announcement of the discovery of glacier evidences in the Mitta Mitta Valley ("On the Meteorology of the Australian Alps," *Trans. Roy. Soc. Vict.*, 1884, p. 23), and Dr. von Lendenfeld's subsequent discovery of traces of ancient glaciers on Mount Kosciusko ("On the Glacial Period in Australia," *Proc. Linn. Soc. N.S.W.*, 1885, p. 45), an interesting controversy has arisen respecting the nature and extent of such glaciation. Having recently undertaken an exploration of Mount Bogong, the highest mountain in Victoria, in company with Dr. von Lendenfeld, for the purpose of discovering further glacier evidences, and so aiding a solution of this important question, I have much pleasure in submitting the following remarks on the results of that expedition. It may be of interest to review my connection with the controversy as a student of physiography resident in the central part of the Australian Alps. During 1880-83, when studying the *flora* of the Australian Alps and collecting herbarium specimens for our venerable Nestor of botanic science, Baron von Mueller, it appeared to me that the date of the introduction of the endemic *florula* of the Australian

[1] Paper read at the Linnean Society of New South Wales, on May 26, 1886, by James Stirling, F.G.S., F.L.S.

Alps (whose affinities were so closely Tasmanian) might safely be centred in glacial movements since Miocene times ("Remarks on Flora of Australian Alps," *Southern Science Record*, 1885, p. 93), provided geological evidences which would lend support to the hypothesis could be obtained; for, as remarked by the ex-President of the Linnean Society, Mr. Wilkinson, F.G.S., F.L.S., in one of his admirable addresses to the Society (President's Address, *Linn. Soc. N.S.W.*, vol. ix., p. 1236), the existence of a semi-tropic flora in South-East Australia during Pliocene times and its subsequent banishment from this region is evidence of a great change of climate in Post-Pliocene times.

In a paper which I have in preparation on the geographic range of the flora of the Australian Alps, it will be shown that many species found there between 2000 and 5000 feet have a wide range, recent researches on the flora of Morocco in Africa, and on that of Kurum Valley, Afghanistan, having disclosed the presence of numerous species of plants common to the Australian Alps; and as Sir Joseph Hooker remarked many years since in his splendid essay on the flora of Australia, "if as complete evidence of such a proportionately cooled state of the intertropical regions were forthcoming as there is of a glacial condition of the temperate zones, it would amply suffice to account for the presence of European and Arctic species in the Antarctic and south temperate regions of both hemispheres on the mountains of intermediate tropical latitudes."

As early as 1882 I discovered many examples of what appeared to be glaciated surfaces in the higher regions of the Australian Alps, notwithstanding that in some areas there were strong evidences of powerful sub-aërial denudation and erosion having taken place during Pleistocene times. *En passant*, I may mention that these apparently glaciated surfaces were seen on the quartz porphyries of Mount Cobboras at elevations between 4000 and 6000 feet; on the metamorphic rocks of Mount Pilot on the Pilot River Valley, down to 3000 feet; and on the granitic rocks of Mount Kosciusko, recently photographed by Dr. von Lendenfeld. Partly, however, from inexperience of glaciated surfaces elsewhere, I hesitated to pronounce authoritatively on them as glacier evidences until further opportunities were afforded me of discovering moraines and erratics at the lower levels. From the fact that my friend, Mr. A. W. Howitt, F.G.S., had not observed any appearances which he could in any way refer to a glacial period analogous with that of the northern hemisphere, unless (as he further remarks) the old lake basins near Omeo might suggest the action of ice ("Geology of North Gippsland," *Q.J.G.S. Lond.*, vol. xxxv. p. 35), I thought it very probable that any pre-existing evidences at the lower levels might have been scoured away by a subsequent pluviatile period ("On a Geological Sketch Section through the Australian Alps," *Trans. Roy. Soc. S.A.*, 1884).

The publication by my friend, Mr. G. S. Griffiths, of a paper on evidences of a glacial epoch in Victoria during Post-Miocene times (*Trans. Roy. Soc. Vict.*, 1884), induced me to re-examine the evidences at the higher altitudes, and to endeavour to follow the traces to lower levels in the Indi and Mitta Mitta Valleys, with the result that I felt justified in making the announcement previously referred to on December 11, 1884, even though some of the phenomena therein ascribed to glacier action might be found on closer scrutiny to have been produced by other causes. The indications taken as a whole were sufficient in my opinion to justify the hypothesis of glaciation, for on no other conceivable theory, as it appeared to me, could the facts as a whole be accounted for; while refrigeration of the area, and the consequent production of glaciers in the valleys of the Australian Alps over wide areas, would harmonise with conclusions deducible from an examination of the flora and fauna. In the beginning of January 1885, Dr. von Lendenfeld ascended Mount Kosciusko and photographed some glaciated surfaces. From the absence of any reference to my previous announcements save a mere reference from the *Southern Science Record* to the snow patches at the higher regions of the Australian Alps, I inferred that Dr. von Lendenfeld was unaware of my previous writings and discoveries, or he would not have stated in his interesting paper "On the Glacial Period in Australia," read before the Linnean Society of N.S.W. during January 1885, that the glacial area was limited to 100 square miles above 5800 feet altitude. On July 9 I published in the *Transactions* of the Royal Society of Victoria the first of an intended series of papers "On the Evidences of Glaciation in the Australian Alps," detailing certain phenomena in the Livingstone Creek and Victoria River Valleys. During the same month a paper, by Captain, now Professor, Hutton, F.G.S., of New Zealand, was read before the Linnean Society of N.S.W., "On the Supposed Glacial Epoch in Australia," being in part a reply to Dr. von Lendenfeld's previous writings concerning a very recent glacier epoch in the southern hemisphere, based upon New Zealand experiences and explorations, and partly an endeavour to show that the *roches moutonnées* and smoothed surfaces on Mount Kosciusko by no means imply, or, to use the actual words of the learned Professor, "it by no means follows, that they were caused by a glacial epoch, because they might equally well be due to greater elevation, combined with greater atmospheric moisture. We are also advised to "distrust an attempt to explain an *isolated phenomenon* by means of a wide-spread cause." Now it appears to me that Captain Hutton would not have assumed the isolation of the phenomena if he had been fully acquainted with the literature of the subject, and especially my announcement previously referred to. I do not propose to join issue with him in respect to the distinction he seeks to draw between a "glacier epoch" and a "glacial epoch," but merely to show that the phenomena of glaciation are not so isolated as his remarks would lead one to suppose he believes them to be. I am led to make these remarks because as a student of physiography I feel very much indebted to Prof. Hutton for the valuable information supplied by his writings concerning the geological structure, flora, fauna, and climatology of New Zealand, and I should be sorry to know that he laboured under any misapprehension as to the nature and extent of the evidences of glaciation in the Australian Alps. Following the publication of the papers of myself and Prof. Hutton we have one by Prof. Tate, F.G.S., of South Australia ("On Post-Miocene Climate in South Australia," *Trans. Roy. Soc. S.A.*, 1885), read before the Royal Society of that colony, in which are stated very clearly the evidences in favour of a glacial period in South Australia. The objections by Mr. Scoullar, Cor. Mem., as to the origin of the glaciated surfaces near Adelaide, viz. that they were caused "by the attrition of blown sand," are also controverted. I have seen some photographs of these glaciated surfaces (sent to me for inspection by Prof. Tate), and they resemble very strongly the glaciated surfaces on Mounts Cobboras and Bogong, to be hereinafter referred to. Dr. von Lendenfeld has also seen some photographs of polished rocks from South Australia, and has no doubt as to the glacier origin of the polishing ("Note on the Glacial Period in Australia," *Proc. Linn. Soc. N.S.W.*, vol. x. p. 330), although he doubts whether the striæ referred to are isochronal with the glacial traces he discovered on Mount Kosciusko. In consequence of a very interesting correspondence on the subject of glacier evidences between Dr. von Lendenfeld and myself, it was arranged that we should make a joint trip to the highest mountain in Victoria, Mount Bogong, and, if time and circumstances permitted, explore the Bogong High Plains to the south, and proceed thence along the main dividing range towards Mount Kosciusko, so that his extensive European Alpine experience and my local geological knowledge might be utilised, and the features discussed on the ground. On January 3, 1886, we met at Snowy Creek junction, a tributary of the Mitta, and on the following three days made the ascent of Mount Bogong from the north, an arduous journey, but still of great interest. Dr. von Lendenfeld has already described our journey in the publications of the Mining Department of Victoria (Mining Registrar's Returns for Quarter ended March), so that it is unnecessary for me to repeat the narrative. Suffice it to say that the evidences of glaciation discovered by us are:—

(1) Erratics in the Reewa River and Snowy Creek Valleys.

(2) *Blocs perches* and smoothed surfaces on Mount Bogong.

(3) Moraines at base of Mount Bogong, Mountain Creek in Reewa River Valley.

The first-named are abundant in the Pleistocene drifts at Snowy Creek, consisting of huge basaltic boulders, &c., in linear extension for miles, as at Granite Flat; the nearest basaltic outliers being fully twenty miles distant on Bogong High Plains, &c.

The second, or what I have called *blocs perches*, are large semi-rounded or sub-angular masses of igneous or rather plutonic rock—hornblende porphyrites—occupying the crests of spurs and sidelings in a regular descending series from near the summit of Mount Bogong, 6508 feet, towards the Reewa Valley, many of them resting upon smoothed surfaces of pegmatite at lower levels. (Mount Bogong is gneissic.)

The last-named are huge masses of angular and sub-angular rocks at the base of Mount Bogong, pronounced by Dr. von Lendenfeld to be undoubted moraines (at an elevation of 1000 feet above sea-level). I may remark that these masses are too extensive and distant from the steep spurs of Mount Bogong to be considered as *talus*; besides which they show evidences of translocation.

I do not purpose entering into a description of further evidences discovered by myself in the Mitta Mitta Valley, at Lake Omeo, or Benambia Creek, &c., in the present paper. There will in due course be communicated a second article on the evidences of glaciation in the Australian Alps, together with a reply to later criticisms. I merely desire to show that the evidences discovered on Mount Kosciusko by Dr. von Lendenfeld are by no means isolated, and that the highest mountain in Victoria, Mount Bogong, presents features which confirm the evidences of glaciation elsewhere, and that there is no *a priori* impossibility of the area of glaciation being more extensive than has been assumed. In conclusion, I would add that taking into consideration the facts supplied to us by the examination of the ancient flora and fauna of Australia as contained in the writings of Prof. Tate, of South Australia, and of Mr. Wilkinson, F.G.S., of New South Wales, and the geological evidences of glaciation over wide-spread areas daily accumulating, it is difficult indeed to resist the conviction that Southern Australia, as well as South America and Southern Africa, and indeed New Zealand, all participated in a period of refrigeration, culminating in an ice-clad region during later Pliocene or Pleistocene times, notwithstanding that many difficulties suggest themselves in endeavouring to work out the problem from mere localised observations.

SORGHUM SUGAR

SOME months ago considerable interest was excited by a report by Mr. Victor Drummond on the production of sugar from sorghum and maize. The report was sent from the Colonial Office to Mr. Thiselton Dyer, with a request that he would state his opinion on the questions raised by Mr. Drummond. For several years the importance of the subject had been recognised at Kew; and in his reply, dated August 10, 1886, Mr. Thiselton Dyer expressed his belief that if sugar could be produced at a cheap rate from sorghum and maize it would entirely take the place of cane and beet sugar, the geographical range of sorghum being far more extensive than that of the sugar-cane proper or of the beet. At the same time he drew attention to the fact that the results summarised by Mr. Drummond had been for the most part derived from laboratory experiments only, and that the question whether the new industry was likely to prosper could not be determined until those results had been tested over wide areas. He also pointed out that some statements in Mr. Drummond's report were at variance with well-known facts in vegetable physiology. Mr. Thiselton Dyer therefore advised that exact information as to the position of the sorghum- and maize-sugar industry in the United States should be obtained through the Foreign Office.

In accordance with this advice, copies of Mr. Drummond's report and Mr. Thiselton Dyer's letter were sent to Sir L. West. By him the matter was put into the hands of Mr. C. Hardinge; and now Mr. Hardinge's report has been published in the series of Foreign Office "Reports on Subjects of General and Commercial Interest." The sorghum-sugar industry has hitherto been conducted on a small scale. In 1884 it was carried on at eight factories, which produced 1,000,000 lbs. in all. The comparative insignificance of this result will be seen when it is stated that in 1885 the quantity of cane-sugar consumed in the United States was 1,170,000 tons. In most cases it was found that the cost of extracting sugar from sorghum exceeded receipts, and at the present time the industry is prosecuted at only two factories—that of the Rio Grande Company and that of the Franklin Sugar Company, whose works have been removed from Ottawa to Fort Scott.

Dr. Wiley, by whom the subject has been thoroughly investigated, attributes the failure of the industry, so far, chiefly to the following causes:—

(1) The difficulties inherent in the plant have been constantly under-valued. By taking the mean of several seasons as a basis of computation, it can now be said that the juices of sorghum, as they come from the mill, do not contain over 10 per cent. of sucrose, while the percentage of other solids in solution is at least 4, thus rendering the working of such a juice one of extreme difficulty.

(2) The chemistry of the process is at present hardly known, and great development is necessary in this direction.

(3) The area of land where the climate and soil are best adapted for the cultivation of sorghum is not nearly so extensive as was at first imagined, and investigation should be made in order to discover in which localities the necessary conditions are most favourable.

(4) Commercial depression and the consequent low prices have affected this industry, and caused failure and losses in cases where all other conditions were favourable.

(5) Lastly, the mechanical treatment of the juice is very imperfect, the machinery used in the mills being quite inefficient for the purposes intended.

In order that the last-mentioned defect might be corrected, the Commissioner of Agriculture decided that experiments for the application of the process of diffusion on a practical scale should be carried on with the best machinery possible, and the direction of the experiments was intrusted to Dr. Wiley. He erected the battery and necessary buildings in connection with the works of the Franklin Sugar Company at Ottawa, Kansas, and the first trial of the process of diffusion was made on October 8, 1885. The general results of the experiments of 1885 show that:—

(1) By the process of diffusion 98 per cent. of the sugar in the cane was extracted, and the yield was fully double that obtained in the ordinary way.

(2) The difficulties to be overcome in the application of diffusion are purely mechanical, and by enlarging the diffusion-cells to a capacity of 130 cubic feet, and by making a few changes in the apparatus, it would be possible to work 120 tons per diem.

(3) The process of carbonatation for the purification of the juice is the only method which will give a limpid juice with a minimum of waste and a maximum of purity.

(4) By a proper combination of diffusion and carbonatation, 95 per cent. of the sugar in the cane can be placed on the market, either as dry sugar or molasses.

When his experiments were ended, Dr. Wiley was instructed by the Commissioner of Agriculture to proceed to Europe for the purpose of inspecting and purchasing such forms of machinery as might appear most useful, also to gain such information as might secure the greatest success in this work; and Mr. Hardinge reports that much useful information, chiefly of a mechanical nature, was obtained by Dr. Wiley during the course of his visits to several of the most important sugar factories in France, Germany, and Spain.

During the season of 1886 further experiments have been carried on at Fort Scott, under the direction of the Department of Agriculture, and the results have not proved to be as satisfactory as was anticipated.

ON THE CUTTING OF POLARISING PRISMS[1]

THE author showed the manner of cutting two new polarising prisms, designed by Ahrens and by himself, and described and figured in the *Phil. Mag.* for June 1886. The Ahrens polariser is a rectangular parallelopipedon of calc-spar having square end-faces, and having its long sides in the proportion of about 1·6 : 1 relatively to the short sides. The square end-faces are principal planes of section of the crystal. Two oblique sections are cut in the prism, being carried through the top and bottom edges of one end-face, and meeting in the horizontal middle line of the others. The dihedral angle between these planes of section is about 32°. The faces are polished and reunited with Canada balsam in the usual way. The advantages claimed for the new prism are: (1) decrease in length, (2) increase in angular aperture, (3) saving of light consequent on non-obliquity of end-faces, (4) minimum of distortion, (5) less spar required than in Hartnack, Glan, or Thompson prisms of same section. Against this are the slight disadvantages of (1) the line of section across end-face, and (2) the use of more spar than a Nicol of equal section. But Mr. Ahrens has recently added a thin covering-glass at the end-face crossed by the line of section, thereby making this line almost imperceptible; and he has also succeeded in finding a new method of cutting the prism in which there is extremely little waste of spar. The other prism designed by the author is a simple modification of the Nicol, giving a wider angle of field. A wedge is cut off

[1] Abstract of a Paper read at the Birmingham meeting, 1886, of the British Association, by Prof. Silvanus P. Thompson.

each end of the calc crystal so as to make the new end-faces almost co-planar with a principal plane of section, and the crystal is cut through along the other diagonal of the sides. The results may be tabulated thus:—

	Ordinary Nicol	Reversed shortened Nicol
Obliquity of end-face	71°	69°
Angle between end-face and crystallographic axis	45	5
Angle between balsam-film and crystallographic axis	45	94

The effect is to throw the blue-iris limit right back, to shorten the prism, and to widen the field. In the discussion that followed, Prof. Stokes remarked that there was no dearth of Iceland spar in Iceland, but that the supply had been limited through ignorance of the extent of the demand. The mine had, however, been bought by the Icelandic Government, and a plentiful supply might therefore be expected.

THE SYMPATHETIC NERVOUS SYSTEM[1]

THE lecturer commenced by giving a short sketch of Bichat's views of the division of life into organic and animal life, and pointed out how that division naturally led to the conception of two separate central nervous systems, the one, the sympathetic, to which all the organic functions are to be referred, the other, the cerebro-spinal, regulating the animal functions. He then pointed out how Remak's discovery of a special kind of nerve-fibre—the non-medullated nerves—associated only with the ganglia of the sympathetic system, tended strongly to confirm Bichat's teaching of the existence of two separate central nervous systems in the human body, each of which communicated with the other by means of its own special kind of nerve-fibres; the cerebro-spinal supplying the sympathetic system with white medullated fibres, and the sympathetic supplying the cerebro-spinal with gray or gelatinous non-medullated fibres. He then continued as follows:—

Even at the present day the teaching of Bichat still very largely holds its ground. It is true that the tendency of modern physiology is to increase the number of centres of action for the organic nerves, which exist in the cerebro-spinal central axis, and therefore to do away with the necessity for a separate independent sympathetic nervous system, yet the automatic actions of isolated organs such as the heart, and the existence of special nerve-fibres in connection with this system, still induce the neurologists of the present day to place the sympathetic nervous system on an equality with the brain or spinal cord. In this lecture to-night I hope to give the death-blow to Bichat's teaching, and to prove to you that the whole sympathetic system is nothing more than an outflow of visceral nerves from certain nerve-centres in the cerebro-spinal system, the ganglia of which are not confined to one fixed position, as is the case with the ganglia of the posterior roots, but have travelled further away from the central axis.

I do not propose to-night to deal with the argument for the independence of the sympathetic nervous system, which is based upon the automatism of such isolated organs as the heart; I have already in various papers given the reasons and arguments why I look upon such automatic movements as due to the automatism of the cardiac muscular tissue rather than to any action of nerve-cells comparable to the nerve-centres of the spinal cord; I shall deal entirely with the anatomical argument, and show you step by step how the nerve-fibres which constitute the sympathetic system can be traced to their origin in the central cerebro spinal axis.

Evidently, in endeavouring to determine by anatomical means whether the sympathetic and cerebro-spinal systems are in reality independent of one another, our attention must necessarily be especially concentrated upon the nature of the connecting-link between the two systems, *i.e.* upon the nature of the rami communicantes. Largely owing to the pre-conceived notions of anatomists, you will find that the rami communicantes are arranged symmetrically in connection with all the spinal nerves of the body. In reality this is far from being the case; the rami communicantes of the thoracic nerves differ from those above them, *i.e.* of the cervical nerves, and from those below them, *i.e.* of the lumbar nerves, in two important particulars: in the first place the corresponding sympathetic ganglion is connected with each thoracic nerve by two rami communicantes; and secondly, these two rami differ in colour, one being gray, *i.e.* composed almost entirely of non-medullated nerves, and the other white, *i.e.* composed essentially of medullated nerve-fibres.

This double nature of the ramus communicans is confined to the region lying between the two large plexuses which supply the anterior and posterior extremities, viz. the brachial, lumbar, and sciatic plexuses; the rami communicantes to the lower cervical and first thoracic nerves, as well as those to the nerves forming the anterior crural and the sciatic, are, on the other hand, single, and are composed only of gray rami. In other words, the sympathetic chain is connected with the central nervous system by means of white rami communicantes only between the second thoracic and second lumbar nerves.

Further, I have been able to trace both the white and gray rami in their journey to the spinal cord by means of consecutive sections of osmic acid preparations, and have found that the gray rami pass out of the sympathetic ganglion as a single nerve, and then ramify in the connective tissue about the vertebral foramina, a portion only reaching the spinal nerve-trunk; the gray fibres of this portion pass mainly along the nerve peripherally, the few which pass centrally never reach the spinal cord, but pass out with the connective tissue which lies in between the medullated nerve-fibres of the anterior and posterior roots, to ramify over and to supply the blood-vessels of the various membranes which inclose the spinal cord.

In fact the gray rami communicantes are peripheral nerves, which partly supply the vertebræ and the membranes of the cord, and partly pass to their destination in the same direction as the efferent fibres of the spinal nerve itself.

So far then I come to these conclusions:—

(1) The sympathetic does not send non-medullated fibres into the cerebro-spinal system, because these fibres all pass out of the nerve-roots before they reach the spinal cord.

(2) White or medullated nerve-fibres constitute the only link between the sympathetic and cerebro-spinal systems, constituting the white rami communicantes.

(3) Consequently the connection between these two nervous systems is limited to the region of white rami communicantes, *i.e.* to the region between the second thoracic and second lumbar nerves.

Further, these conclusions are borne out when we attempt to follow the white rami commnnicantes into the central spinal axis by means of their structural peculiarities; sections of osmic preparations show that each white ramus is composed chiefly of very small medullated nerve-fibres, varying in size from 1·8 μ to 3·6 μ, very much smaller, therefore, than the large medullated nerves which form the bulk of the anterior roots of the spinal nerves, these latter varying between 14 μ to 20 μ or even larger. Clearly then the fibres of the white ramus communicans ought to show very conspicuously among the large fibres of the anterior roots whenever they are present in those roots. I have cut sections of the anterior roots of all the spinal nerves in the dog, and have found, as I show you on this screen, that these very fine medullated nerve-fibres make their appearance for the first time in the anterior roots of the second thoracic nerve; they are found in large quantities in all the anterior roots between the second thoracic and second lumbar, and then again the anterior roots immediately below the second lumbar are free from such groups of very fine fibres. We see then that exactly corresponding to the presence of white rami communicantes in the thoracic region we find groups of characteristic fine medullated fibres existing in the anterior roots, fibres which clearly form part of the white ramus communicans, and confirm by their presence the conclusion already arrived at, viz. that the nerves which pass from the spinal cord into the sympathetic system are limited to the thoracic region of the cord.

We can now go a step further and argue in the reverse direction that the presence of groups of these very fine medullated fibres in the anterior roots of any nerve implies the existence of nerve-fibres belonging to the same system as the white rami communicantes or rami viscerales, as we may now call them. Examination shows how just is this argument, for I find that the same groups of fine nerve-fibres suddenly appear again in the anterior roots of the second and third sacral nerves, and can be traced into that well-known nerve which passes from the second and third sacral nerves into the hypogastric plexus to

[1] Abstract of Lecture at the Royal Institution on June 4, 1886, by Walter H. Gaskell, M.D., M.A., F.R.S.

supply the rectum, bladder, and reproductive organs; a nerve, therefore, which may be looked upon as the white ramus communicans of the sympathetic ganglia which form the hypogastric plexus.

Again, in the cervical region, although such groups of fine fibres are absent from the anterior roots of all the cervical nerves, yet they form a conspicuous part of the upper roots of the spinal accessory nerve, and upon tracing them outwards I find that they separate entirely from the large fibres of the accessory which form its external branch to pass as the internal branch into the ganglion trunci vagi (Fig. 2). Here, then, we see in the upper cervical region that the internal branch of the spinal accessory nerve is formed on the same plan as a white ramus communicans, the ganglion belonging to which is the ganglion trunci vagi.

Among the cranial nerves we find, especially in the vagus, glosso-pharyngeal, and chorda tympani, groups of fine nerve-fibres belonging to the same system. We can therefore say that the communication between the so-called sympathetic and cerebro-spinal systems is not symmetrical throughout, but consists of three distinct outflows of characteristic visceral nerves, viz.: (1) cervico-cranial; (2) thoracic; (3) sacral; the break of continuity corresponding to the exit of the nerve plexuses which supply the upper and lower extremities.

These medullated visceral nerves then pass out from the central nervous system into the various ganglia of the sympathetic, and it is possible that these latter ganglia bear the same kind of relation to them as the ganglia on the posterior roots bear to the sensory nerves. Before, however, we can accept this view, it is absolutely necessary to account for the non-medullated nerves which arise from the sympathetic ganglia Now it is hopeless to follow, by anatomical means, any special nerve-fibre through the confusion of a ganglion. What we cannot effect by anatomical methods we can by physiological. If we find two nerves, one of which enters a ganglion and the other leaves it, and we find their function absolutely the same on both sides of the ganglion, we have a perfect right to conclude that we are dealing with the same nerve in different parts of its course. Thus, in the case of the posterior root ganglion, the same sensory nerves are found on each side of the ganglion, although they are in connection with nerve-cells of the ganglion itself.

So also with the sympathetic ganglia: we know, for instance, that the nerves which increase the rate and strength of the heart's beat pass to the ganglion stellatum along the rami communicantes of the second and following thoracic nerves, and we know also that the same nerves pass to the heart from the ganglion stellatum, from the annulus of Vieussens, and from the inferior cervical ganglion. Now, seeing that these nerves are known to pass out of the cord in anterior roots, and from thence into the white rami communicantes of the upper thoracic nerves, it follows that they are medullated in this part of their course, and are to be found among the bundles of very fine medullated nerves which we have seen are characteristic of the anterior roots of this region and of the white rami communicantes.

We can then say with certainty that the accelerator nerves enter the ganglia stellata as fine white medullated nerves. I am also able to say with absolute certainty that the accelerator nerves in that part of their course which lies between the chain of sympathetic ganglia and the heart are entirely composed of

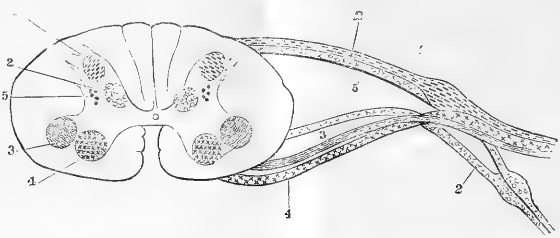

FIG. 1.—Diagram of section of spinal cord to show the various groups of nerve-cells in the gray matter, and the formation of a spinal nerve with its sympathetic ganglion. 1, cells of posterior horn and somatic sensory nerves. 2, cells of Clarke's column and ganglionated splanchnic nerves. 3, cells of lateral horn and non-ganglionated splanchnic nerves. 4, cells of anterior horn and somatic motor nerves. 5, solitary cells of posterior horn and splanchnic sensory nerves.

non-medullated fibres. I know no other bundle of nerve-fibres which is so absolutely free from medullated nerves: in other words, nerve-fibres of the same function enter a sympathetic ganglion as white medullated fibres, and leave it in increased numbers as gray non-medullated nerves.

Throughout we find the same fact—all the vasomotor nerves behave in exactly the same manner as the accelerators of the heart. In all cases the non-medullated fibres of the sympathetic are simply the fine medullated visceral nerves which have passed from the spinal cord in one or other of the three visceral outflows and lost their medullary sheath in their passage through the ganglia of the sympathetic system; together with that loss of medulla they have increased in number by division.

Seeing, then, that the non-medullated (so-called sympathetic) nerve-fibres are throughout modified medullated (so-called cerebro-spinal) fibres, and do not, therefore, arise in the sympathetic ganglia, we may fairly look upon the sympathetic ganglia as bearing the same kind of relation to the visceral nerves that the ganglia of the posterior roots bear to the ordinary sensory nerves. This conception is remarkably confirmed by the observations of Onodi, who has shown that the ganglia of the sympathetic are developed in close connection with the posterior root ganglia, and travel further away from the central axis as the animal grows.

Finally, the meaning of the sympathethic as a simple outflow of ganglionated visceral nerves from certain portions of the spinal cord and medulla oblongata is, to my mind, conclusively settled by the intimate relationship which exists between the structure of the spinal cord and the presence or absence of rami viscerales. In the gray matter of the spinal cord we find, as shown in the accompanying diagram, certain well-defined groups of nerve-cells, viz., *a*, a group of large nerve-cells in the anterior horn (4 in Fig. 1); these are known to be the origin of ordinary motor-fibres (4); *b*, a group of nerve-cells (3) split off from this and forming the lateral horn; *c*, a group (2) known as Clarke's column; and *d* and *e*, two sets of nerve-cells, (4) and (5), in the posterior horn connected with sensory nerves. All these groups of nerve-cells are found along the whole length of the spinal cord, except those of Clarke's column. Their connection with nerve-fibres of different functions is known, except those of Clarke's column. Thus both sets in the anterior horn are connected with ordinary motor-nerves; both sets in the posterior horn with ordinary sensory nerves. Now, Clarke's column is limited to certain definite regions of the cord, being conspicuous: firstly, between the second thoracic and second lumbar nerves; secondly, at the top of the cervical region and extending into the cranial region; and, thirdly, an isolated patch in the sacral region. In other words, its cells correspond exactly in position to the distribution of the white rami communicantes, so that, corresponding to the variation of this cell-group, we find variations of the number of very fine medullated fibres in the anterior roots, and we find corresponding variations in the white rami communicantes, which latter, as I have told you, are the only true connections of the cerebro-spinal nerve-centre with the sympathetic. In other words, we have driven home to their origin these visceral nerve-fibres, and we find that they do not arise from any nerve-cells outside the brain and spinal cord, but from a definite nerve-group within the spinal cord.

We can, I think, go further than this, and say, with Bichat, that two nerve-systems do exist—the one for organic, and the other for animal, life. These two, however, are not separate and distinct, but form parts of the same central nervous system. Looking at this diagram of the upper cervical region of the cord, we see that the voluntary striped muscles may be divided into two groups, according to their nerve-supply, viz. a group supplied by the anterior (4), and one by the lateral horn of nerve-cells (3), and we know also that these two groups of nerve-cells separate from one another more and more as we pass into the brain region. So that we find for the muscles of the face a distinct separation of two groups, viz. (1) those which move the eyes and the tongue—these are supplied by nerves which arise from the continuation of the anterior horns; and (2) the muscles of expression and mastication, the nerves of which arise from the continuation of the lateral horn; and remembering how the smile, the laugh, and the snarl, as well as the action of swallow-

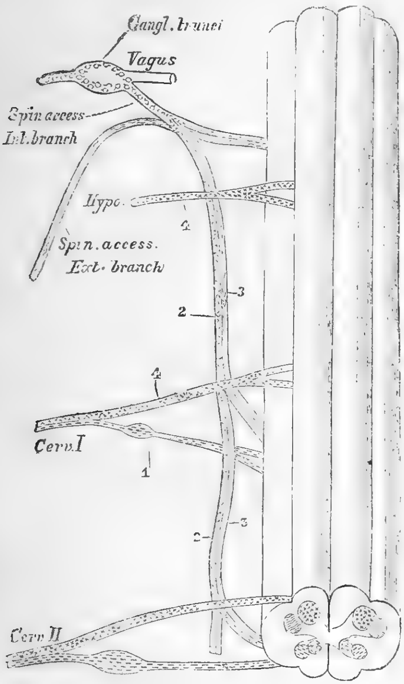

FIG. 2.

ing, are at the bottom only modified respiratory movements, we see that Charles Bell was not so far wrong when he inserted a lateral or respiratory system of nerves in between the anterior and posterior roots. This insertion is actually to be seen at the upper part of the cervical cord (Fig. 2) where a separate nerve is formed by elements which arise laterally, known as the spinal accessory; and what is most striking is this fact, that in this region the fine medullated fibres (2 in Fig.) are found only in connection with these lateral motor nerves, and not with the anterior motor, so that not only do these lateral or respiratory tracts supply special muscles with motor nerves, but these motor nerves have a closer relationship to the visceral nerves than other motor nerves. What is true of the upper cervical region is true also of the medulla oblongata. Here, again, the visceral fine medullated nerves are closely connected with the motor fibres which arise from the lateral horn, *e.g.* the chorda tympani and the facial. Undoubtedly this particular group of muscles has some closer relationship to the viscera than other trunk muscles, and that relationship is explained immediately if we can accept and extend van Wijhe's investigations, viz. that in the cranial region the muscles which are supplied by the third, fourth, sixth, and twelfth cranial nerves are derived from the myotomes, while the muscles supplied by the seventh and fifth cranial nerves are derived from the lateral plates of mesoblast.

In fact we may look upon the body as composed of two parts—an outside or somatic part, and an inside or splanchnic part. Each part has its own system of voluntary muscles; each part is supplied by nerves arranged on the same plan, viz. a ganglionated and non-ganglionated portion; and each part has its own individual centres of action, the inside portion of the gray matter of the spinal cord containing the centres for the splanchnic roots (2, 3, 5, in Fig. 1), *i.e.* the centres of organic life; the outlying horns the centres for the somatic roots (1 and 4), *i.e.* centres for the animal life. It is a strange and suggestive fact that these two sets of centres are not arranged symmetrically along the spinal axis, but that two great breaks occur in which the centres of organic life fall into the background in comparison to those of animal life. These two great breaks correspond to the origin of the nerves for the legs and arms, and suggest that the formation of the limbs in the originally symmetrical ancestor of the Vertebrata—*i.e.* the large outgrowth of somatic elements in two definite portions of the body—caused of necessity a corresponding increase in the centres for animal life, while there was no necessity for a corresponding increase in the centres for organic life. The oldest part of us is undoubtedly the vital part; those organs and their nervous system by which the mere act of existence is carried on. With these two there may have been originally a symmetrically segmental arrangement of locomotor organs. Such symmetry, however, went for good when it was found more convenient to concentrate the locomotor machinery into the anterior and posterior extremities, and with the asymmetrical arrangement of the locomotor organs disappeared also the symmetry of the central nervous system. This correspondence between the plan of the central nervous system and the development of the extremities is, to my mind, strongly in favour of the view which I have put before you to-night. In conclusion, I thank you for the kindness with which you have listened to me, and hope that I have succeeded in convincing you that Bichat's teaching of an independent sympathetic system is finally dead.

SCIENTIFIC SERIALS

Revue d'Anthropologie, troisième série, tome 1, 1886, Paris.—On the colour of the eyes and hair in different parts of France, by M. Topinard. This paper will form the introduction to a comprehensive work, in which the author proposes to consider the various methods followed in other countries in collecting the necessary data for determining the racial significance of these physical characteristics. In France, where good charts of stature have been drawn up for the several departments, no statistical observations have been made in regard to the colour of the skin, eyes, and hair. This M. Topinard considers at length, both in its significance as a racial characteristic, and in regard to the modifications which it undergoes at various ages, and from different local surroundings. In considering the more or less typical series of colour, the writer draws attention to the extreme rarity in Europe of greenish eyes. In Germany, Prof. Virchow states that, among 6,000,000 persons, green eyes were noted only in six cases. Chinese annals record, however, that green eyes are met with in parts of Asia; and Pallas notes a similar fact in regard to Siberia. In concluding his exhaustive *résumé* of what has been done in other countries, M. Topinard states that he has addressed letters to the members of the French Association for the Promotion of Science, begging their co-operation in the collection of the necessary data for drawing up statistical tables of the relative proportion of the different shades of colour of the eyes and hair in various parts of France.—Illyrian anthropology, by Dr. R. Zampa. The author, who is well known for his able contributions to the ethnography of Italy, has turned his attention to the anthropological character of the Illyrian races, who occupied the South Danubian and other eastern trans-Alpine lands, to which tradition points as the original home of the earliest settlers of the Adriatic provinces of central and lower Italy. Dr. Zampa denies that the Illyrians were ever a homogeneous race, and he points out that while those of the north retained through the ages the character of savage marauders and pirates, the South Illyrians, four centuries B.C., had been thoroughly amalgamated with the Macedonian and Epirote nations, adopting the pre-Hellenic form of speech of those peoples, which still lingers in the spoken tongue of the modern Albanians. After the incursions of Finns and Slavs into the Balkan and Danube territories, in the sixth and seventh centuries, the remnant of Illyrian and other primitive races that escaped extermination were comprised under the general name of Albanians; and Dr. Zampa believes that in the mountainous districts of Scutari we find the purest representatives of the ancient Albanian race. In this region, therefore, he has sought the data necessary for the elaboration of the comparative anthropological researches of the ethnic relations and differences existing between the Italian and other branches of the Albanian peoples. The author gives at length the results of his measurements of several series of crania obtained in Dalmatia, comparing them with those taken from living subjects; and although it cannot be said that his researches decide the question whence the Albanian Italians derive their origin, they throw important light on the early history of the primitive races of the Balkan Peninsula, and on their gradual amalgamation with the numerous invaders and alien settlers who, in the course of ages, have occupied the lands of the ancient Illyrians.—On trephining, as practised in Montenegro, by M. Védrènes. The question of prehistoric trepanning, which first excited attention about ten years ago, has led to the consideration of the hitherto almost unnoticed fact that cranial trephining has been practised in Europe from the most remote ages to the present day. Indeed, according to M. Védrènes, the operation is also of frequent occurrence among the natives of Aurès, in Algiers, where it is held in high esteem as being both safe and beneficial. Here it is generally used to arrest the acute pains which are frequently experienced after severe injuries to the head; a portion of bone, about a centimetre in diameter, being cut out to admit of the introduction of a sponge for the removal of extravasated blood. A precisely similar operation is common in Montenegro, where, as at Aurès, it is performed by the members of certain families, amongst whom the profession of trephining has flourished for ages, and been respected as an hereditary distinction transmissible from father to son. The author draws attention to the curious circumstance that the practice of trephining and implicit faith in its efficacy have kept their ground, not merely in the semi-barbarous populations of Algiers and the Balkan mountain districts, but even among the miners of Cornwall, who have continued, to our own times, to regard this operation as the only adequate mode of treatment in various injuries to the head.—Contribution to the history of anomalies of the muscles, by M. Ledouble. The author considers that, while the pyramidalis abdomilis, peroneus, palmaris, plantaris, and psoas parvus are more usually absent than any of the other muscles, the last-named is so frequently missing, that some writers have even assumed that its presence was abnormal. It is more frequent in women than in men; but for this peculiarity, as well as for the variations observable in the mode of insertion of psoas magnus and parvus, the author does not attempt to offer any explanation; his paper giving simply the result of his own observations of muscular anomalies in the lower animals, as well as in man.

SOCIETIES AND ACADEMIES

London

Royal Society, November 25.—"On Jacobi's Figure of Equilibrium for a Rotating Mass of Fluid." By G. H. Darwin, M.A., LL.D., F.R.S., Fellow of Trinity College, and Plumian Professor in the University of Cambridge.

Jacobi was the first to prove that a mass of fluid in the form of an ellipsoid, with three unequal axes, is in equilibrium when rotating about the smallest of the three axes. The determination of the axes in terms of the angular velocity of the system has hitherto been left in an analytical form, not well adapted for numerical calculation. In the present paper the formulæ are brought into a shape involving elliptic integrals, and, by the aid of Legendre's tables, a table of solutions is calculated.

If σ be the density of the fluid, ω the angular velocity, and $\frac{4}{3}\pi\sigma$ the mass, then, when $\omega^2/4\pi\sigma = \cdot 09356$, the Jacobian ellipsoid is a revolutional figure with axes $1\cdot 1972$, $1\cdot 1972$, $0\cdot 6977$. For smaller values of the angular velocity the first axis increases and the two latter diminish. For example, when $\omega^2/4\pi\sigma = \cdot 07047$, the axes are $1\cdot 899$, $0\cdot 811$, $0\cdot 694$.

When the angular velocity is infinitely slow, the ellipsoid becomes infinitely long and thin, and tends to assume a figure of revolution about its greatest axis.

Although the angular velocity diminishes as the length of the ellipsoid increases, yet the moment of momentum continually increases, and becomes infinitely great when the ellipsoid is infinitely long.

The kinetic energy at first increases with the length, attains a maximum, and then diminishes, so that when the ellipsoid is infinitely long it vanishes.

The intrinsic energy, however, always increases, so that the total energy of the system has no maximum, and continually increases with the length of the ellipsoid.

Approximate formulæ are given, which assume a very succinct form when the ellipsoids are long.

December 9.—"A New Method for the Quantitative Estimation of the Micro-organisms present in the Atmosphere." By Percy F. Frankland, Ph.D., B.Sc. (Lond.), F.C.S., F.I.C., Assoc. Roy. Sch. of Mines.

The author commences by describing some of the more important methods which have been elaborated for the bacterioscopic examination of air. In these he includes the experiments of Pasteur, Tyndall, Freudenreich and Miquel, Koch, and Hesse. After pointing out the several advantages and disadvantages which attend these processes, he describes a new method which he has devised, in which he has endeavoured to overcome some of the objections to which the others are open. The following is a brief description of the author's method:—

A known volume of air is aspirated through a glass tube containing two sterile plugs, consisting either of glass-wool alone, glass-wool and fine glass-powder, glass-wool coated with sugar, or sugared glass-wool and fine sugar-powder. The plugs are so arranged that the first one through which the air is drawn is more pervious than the second. After a given volume of air has been aspirated, the two plugs are transferred respectively to two flasks, each containing melted sterile gelatine-peptone, which are then plugged with sterile cotton-wool stoppers. The plug is then carefully agitated with the gelatine until it has become completely disintegrated, care being taken to avoid any frothing of the gelatine; and the latter is then slowly congealed so as to form an even film over the interior surface of the flask.

On incubating these flasks at a temperature of 22° C., in the course of from four to five days the colonies derived from the organisms contained in the plugs make their appearance, and can be readily counted and further examined. A very large number of experiments are recorded which were made to test the accuracy of the "flask-method." For this purpose experiments were made, in which sometimes single, and sometimes double plugs were employed, and it was almost invariably found that all the organisms were deposited on the first plug; the second plug, in the very exceptional cases when it did yield anything, rarely gave rise to more than a single colony.

It was also found that, whereas in out-of-door experiments a *blank* Hesse-tube, exposed side by side with the one through which air was being aspirated, contained a number of organisms,—thus creating an important source of error in the quantitative results obtained by Hesse's method,—in the "flask-method" such blank tubes rarely contained any organisms; and even when such was the case, but a very small proportion of those present in the actual tube.

This shows that, whereas in Hesse's apparatus any disturbance of the air during the experiment vitiates the accuracy of the result, in the "flask-method" no such effect is produced.

On the other hand, in the absence of aërial currents, the blank Hesse-tube contained only a few organisms, and a remarkable uniformity was found in the results obtained by Hesse's method and that of the author. This is important, not only as showing the quantitative accuracy of the "flask-method," but in clearly demonstrating that the organisms present in the air exist in an *isolated* condition, and not in aggregates, as suggested by Hesse, for it will be remembered that the plug is violently agitated with the gelatine-peptone in the flask, during which operation such aggregates would undoubtedly be broken up wholly or at least partially. It would therefore be reasonable to expect that the "flask-method" would yield a larger number, and possibly a far larger number, of colonies than found in Hesse's tubes; but since, on the contrary, the numbers agreed under the circumstances described in so striking a manner, it is shown convincingly that they exist in an isolated condition.

The paper is illustrated by photographs and drawings.

Of the numerous experiments recorded in the paper, the following series made at St. Paul's may be specially referred to, both as illustrating the quantitative accuracy of the process, as well as showing how it may be employed in ascertaining the distribution of micro-organisms in the atmosphere:—

November 19, 1886		Number of micro-organisms found in 10 litres of air
St. Paul's Churchyard		47
Stone Gallery	No. 1	40
	No. 2	35
Golden Gallery	No. 1	10
	No. 2	11
	No. 3	11

The following are the principal advantages which the author claims for the "flask-method":—

(1) The process possesses all the well-known advantages attaching to the use of a solid cultivating medium.

(2) The results, as tested by the comparison of parallel experiments, can lay claim to a high degree of quantitative accuracy.

(3) The results, as tested by control experiments, are not appreciably affected by aërial currents, which prove such a disturbing factor in the results obtained by some other methods.

(4) The collection of an adequate sample of air occupies a very short space of time, so that a much larger volume of air can be conveniently operated upon than is the case with Hesse's method. Thus, whilst the aspiration of 10 litres of air through Hesse's apparatus takes about three-quarters of an hour, by the new method about 48 litres can be drawn through the tube in the same time; whilst a better plan is to take two tubes and alternately draw a definite volume of air through each, as by this means duplicate results are obtained.

(5) As the whole plug upon which the organisms from a given volume of air are deposited is submitted to cultivation without subdivision, no error is introduced through the multiplication of results obtained from aliquot parts, and all the great difficulties attending equal subdivision are avoided.

(6) The risk of aërial contamination in the process of *flask-cultivation* is practically *nil*.

(7) The apparatus required being very simple and highly portable, the method is admirably adapted for the performance of experiments at a distance from home, and in the absence of special laboratory appliances.

"Further Experiments on the Distribution of Micro-organisms in Air (by Hesse's method)." By Percy F. Frankland, Ph.D., B.Sc., F.C.S., F.I.C., and T. G. Hart, A.R.S.M.

The authors record a number of experiments, made with Hesse's apparatus, on the prevalence of micro-organisms in the atmosphere. The results are intended to form a supplement to those already obtained by one of the authors, and published in the last number of the Society's *Proceedings*. The greater number of the experiments have been performed on the roof of the Science Schools, South Kensington, the air of which has now been under observation at frequent intervals during the present year. The authors point out the variations, according to season, which have taken place in the number of micro-organisms present in the air collected in the above place. The average results obtained were as follows:—

1886	Average number of micro-organisms found in 10 litres of air by Hesse's method
January	4
March	26
May	31
June	54
July	63
August	105
September	43
October	35

Experiments are also recorded showing the enormous increase in the number of micro-organisms present in the air of rooms consequent on crowding. In illustration of this point the authors cite a series of experiments made in the library of the Royal Society during the evening of the *conversazione* in June last, when the following results were obtained:—

Royal Society's Library	Number of micro-organisms found in 10 litres of air
June 9, 1886, 9.20 p.m.	326
,, 10.5 ,,	432
June 10, 1886, 10.15 a.m.	130

In addition to determining the number of organisms present in a given volume of air, the authors have also, in each case, roughly estimated the number falling on a given horizontal surface by exposing dishes filled with nutrient gelatine and of known superficial area, as in the experiments previously published.

Society of Antiquaries, December 9.—Dr. John Evans, President, in the chair.—Mr. J. Allen Brown, F.G.S., F.R.G.S., read a paper on his discovery of a Palæolithic workshop floor of the Drift period near Ealing. He pointed out that the discovery of this Palæolithic working site fully confirmed his previous observations of the higher river-drift deposits in North-West Middlesex, *i.e.* that such old floors or former land surfaces are often discernible therein, and that such habitable spots have been preserved in different parts of the Thames Valley, though they have frequently been disturbed, removed, and re-deposited in other places by the changing course and curves of the wider river of the past, and by floods and other conditions of the severer climate which then prevailed. This Palæolithic workshop floor, which is about 100 feet above the present bed of the Thames, and about two miles distant from it, is situated near the junction between the Creffield Road and Mason's Green Road, Acton; the floor is here about 6 feet from the surface, with a steeper slope to the river than the present surface; it is covered to this extent with sand, brick earth, and trail deposits. At this site, on an area of about 40 feet square, were found nearly 600 unabraded worked flints, including long spear or javelin heads from 5 to 6 inches long, neatly trimmed to a point, and of the same form as those of obsidian, &c., now employed by the natives of New Caledonia, the Admiralty Islands, and Australia, for insertion into the shafts of their spears, to which they were fixed by lashings, &c. There were also shorter ones, not only wrought along the sides to the point where the flake required trimming, but also neatly chipped at the butts into rough rudimentary tangs. Such spear-heads have not only been described by Messrs. Lartet and Christy from the cave of Le Moustier, in the Dordogne, but have been met with in the alluvial deposits of the Somme at Abbeville, the Seine, and other French rivers, as well as by Dr. J. Evans, from Mildenhall, &c. Roughly wrought hatchets, axes, or choppers formed from flakes chipped on one or both faces to a cutting edge were also found rather abundantly on the floor. They are probably some of the earliest rude celt forms, and have been found also in other gravel deposits of the district. At the Creffield Road site they were discovered both finished and unfinished, and correspond with similar tools described by Dr. Evans from the high-level deposits at High Lodge, Mildenhall, Santon Downham, and Fisherton, near Salisbury, &c., as well as in the high-level Quaternary drift at Sauvigny (Loire) described by Dr. H. Jacquinot, and in the deposits of Le Moustier (Dordogne), &c. Some of the specimens exhibited were worked on both faces and pointed, thus approaching the Saint Acheul types, which M. G. de Mortillet considers as belonging to the earliest drift series, that of the Chelléen epoch; they have also been described from other places in North-West Middlesex, as well as by Prof. Boyd-Dawkins from Wookey Hole, and by Dr. Evans from Biddenham, Bedford, Thetford, &c. Among the most interesting implements exhibited were borers, awls, or drills, some being large enough for boring wood; while others were sufficiently small for piercing bone needles, and also flints with neatly chipped symmetrical depressions, which it is believed were used as shaft-smoothers, or spokeshaves, like those lately exhibited in Mr. Dunn's collection of Bushman and Hottentot stone implements at the Colonial and Indian Exhibition. Large numbers of knives formed from flakes, often neatly worked on the edge with fine secondary work, and also saws chipped with a distinctly serrated edge, were exhibited from this site, with other tools apparently intended to be used as chisels, &c. L rge numbers of waste flakes, as well as blocks of flint which had been worked upon, were also found at this spot; and in Ealing, about two miles distant, in a deposit of about the same age, a large boulder of metamorphic rock, concave on both faces and roughened and scored in the hollows from use, was met with; it is 7½ inches long: and a quartzite boulder which fits the hollows was found near it, in fine gravel. They are the first pounding-stones discovered in the drift deposits. The author—after describing the various typical forms of the flint implements from the river-drift deposits of Ealing, Acton, Hanwell, Dawley, &c., in his large collection, and their respective ages, as educed from the position or level at which they have been found, as well as their condition, whether abraded or unrolled, with other surface features of the specimens—showed that the flint implements from the Thames Valley may be divided into three groups, decreasing in age from the highest beds of drift to those lower in the valley as the process of erosion and part infilling of the valley continued. The implements and flakes found at the Creffield Road working site, which are as sharp and unabraded as on the day they were struck from the cores, were compared both as to their forms and associated Quaternary fauna with those from the upper drift of England and France. When considered in reference to M. G. de Mortillet's classification of four divisions—*i.e.* the Chelléen or Acheuléen, with which remains of the older Quaternary fauna, such as *E. antiquus*, *Rhinoceros hemitœchus*, hippopotamus, large cave-bear, &c., are associated; the Moustierien characterised by lance-heads, chopping-tools, &c., formed, from flakes, with the later Quaternary fauna, such as the *E. primigenius*, *Rhinoceros tichorhinus*, reindeer, &c.; and the less ancient divisions of the Solutréen and Magdalénien—Mr. Allen Brown showed, from the discovery of *Rhinoceros hemitœchus*, of hippopotamus, and an older form of deer, &c. (though at the mid-terrace stage of the erosion of the valley), by Colonel Lane-Fox and others, that the fabricators of the human relics discovered at the workshop site at Creffield Road lived contemporaneously with some of the older Quaternary fauna, and that they may therefore be considered as older than the epoch Moustierien, and may perhaps belong to the Chelléen period; but it is evident most of them were intended for mounting in handles or shafts, as such implements are hafted now by Australians and others, and not as "the *coups de poings*," or fist-strikers, of M. de Mortillet; and that, since they were made, the vast mass of matter represented now by the space between the 100-foot contour and the present bed of the Thames, two miles away, has been eroded. A large collection of objects from the workshop floor were exhibited, and many other flint implements from North-West Middlesex, illustrating the author's classification.

Geological Society, December 1.—Prof. J. W. Judd F.R.S., President, in the chair.—Henry Howe Arnold-Bemrose, Richard Assheton, Francis Arthur Bather, Rev. Joseph Campbell, John Wesley Carr, Thomas J. G. Fleming, Thomas Forster, Edmund Johnstone Garwood, George Samuel Griffiths, Dr. Frederick Henry Hatch, Robert Tuthill Litton, Frederick William Martin, Richard D. Oldham, Forbes Rickard, Albert Charles Seward, Herbert William Vinter, and Charles D. Walcott were elected Fellows of the Society.—The President announced that he had received from Prof. Ulrich, of Dunedin, New Zealand, the announcement of a very interesting discovery which he had recently made. In the interior of the South Island of New Zealand there exists a range of mountains, composed of olivine-enstatite rocks, in places converted into serpentine. The sand of the rivers flowing from these rocks contains metallic particles, which, on analysis, prove to be an alloy of nickel and iron in the proportion of two atoms of the former metal to one of the latter. Similar particles have also been detected in the serpentines. This alloy, though new as a native terrestrial product, is identical with the substance of the Octibeha meteorite, which has been called octibehite. Prof. Ulrich has announced his intention of communicating to the Society a paper dealing with the details of this interesting discovery—which is certainly one of the most interesting that has been made since the recognition of the terrestrial origin of the Ovifak irons.—The following communications were read:—On a new genus of Madreporaria—*Glyphastræa*, with remarks on the *Glyphastræa forbesi*, Edw. and H., sp., from the Tertiaries of Maryland, U.S., by Prof. P. Martin Duncan, M.B., F.R.S.—On the metamorphic rocks of the Malvern Hills, part 1, by Frank Rutley, F.G.S., Lecturer on Mineralogy in the Royal School of Mines. Part 1 is the result of conclusions arrived at in the field; part 2 will be devoted to a microscopic description of the rocks. The author referred especially to the paper by the late Dr. Holl, whose work he, in the main, confirmed. Dr. Holl's object was to demonstrate that the rocks which had hitherto been treated as syenite, and supposed to form the axis of the hills, were in reality of metamorphic origin, and belonged to the pre-Cambrian. Mr. Rutley restricted his observations to the old ridge of gneissic syenite, granite, &c., which constitutes the main portion of the range, and, reversing the order of his predecessor, commenced at the north end of the chain. He considers that the beds of crystalline rock, mostly of a gneissic character, in the old ridge have been disposed in a synclinal flexure, which stretched from the north end of the chain to the middle of Swinyard's Hill, where they receive an anticlinal flexure, and are faulted out of sight. The length of this synclinal fold would be over 5½ miles. The lithological evidence is in favour of the rocks forming the north part of Swinyard's Hill being a repetition of those on the Worcestershire Beacon. We might expect to find the older beds having the coarsest granulation, and being even devoid of foliation, and this is what occurs on the Malverns, where the northern hills are made up of the coarsest rocks, with finer schistose beds towards the south; the exception is at Swinyard's Hill; hence there are two groups of coarsely crystalline rocks at either extremity of the presumed synclinal. The contrast between these and the fine-grained rocks of the other portions of the range has already attracted attention. The most northern of the coarse-grained masses is cut off towards the south by a fault near the Wych, while the other lies between a fault on the north side of the Herefordshire Beacon and the before-mentioned fault on Swinyard's Hill. The metamorphic rocks of the Malverns seem, therefore, to be divisible into three series, extending from the North Hill to Key's End; a Lower, of coarsely crystalline gneissic rocks, granite, syenite, &c.; a Middle, of gneissic, granitic, and syenitic rocks of medium and fine texture; and an Upper, of mica-schist, finely crystalline gneiss, &c. A diagrammatic section shows the distribution of these: the northern block, extending as far as the Wych, consists of the Lower and the lower part of the Middle; the central block, from the Wych to the fault in Swinyard's Hill, consists chiefly of the Lower and upper Middle, but with a portion of the Lower at the south end; the southern block, south of the fault on Swinyard's Hill, consists wholly of the Upper series. How far the foliation of these rocks and their main divisional planes represent original stratification must, the author thought, remain an open question. It has been held that the strike of foliation lies parallel to the axes of elevation; but this is far from being the case in the Malverns. Still a once uniform strike may have been dislocated by repeated faulting. The author further discussed the general question of how far foliation may or may not coincide with planes of sedimentation. He admitted that the absolute conversion of one rock into another by a process of shearing has been shown to occur, but doubted its application in this case. Although he is inclined to believe that the divisional planes, with which the foliation appears to be parallel, may be planes of original stratification, yet, as a matter of fact, they are nothing more than *structural planes of some sort*, between which the rocks exhibit divers lithological characters.—On fossil chilostomatous Bryozoa from New Zealand, by Arthur Wm. Waters, F.G.S. The fossil Bryozoa described in the present paper are from the localities of Petane, Waipukurau, Wanganui, and some simply designated as from the neighbourhood of Napier. The first three represent deposits of a well-known position, which was considered Miocene by Tenison-Woods, but which Prof. Hutton (*Quart. Journ. Geol. Soc.*, vol. xli.) has more recently called Pliocene. Some others, sent over as from "Whakati," are thought to be from Waikato. The genus *Membranipora*, which is largely represented from near Napier, is not one of the most useful palæontologically, because the shape of the opesial opening only, and not the oral, is preserved, and also the appearance of the zoœcia is often remarkably modified by the ovicells, which, however, are frequently wanting, and in many well-known species have never been found. The author pointed out that in the commoner and best-known species of Bryozoa the amount of variation is recognised as being very great, and considered that in the face of this there is too great a tendency to make new species on slight differences which may be local variations, and that even in some cases, instead of the description referring to a species, it may be that only a specimen has been described. A list of New Zealand Bryozoa has been drawn up by Prof. Hutton, and our knowledge of the New Zealand and Australian Bryozoa is being constantly increased by MacGillivray, Hincks, and others; nevertheless, enough is not yet known to fix the exact age by means of the Bryozoa alone, but the large number of species entirely identical with those living in the neighbouring seas, and the general character of the others, show that the deposits must certainly be considered as of comparatively recent date. Out of the seventy-eight species or varieties, sixty-one are known living, twenty-nine of these from New Zealand seas, forty-eight from either New Zealand or Australian waters, and twenty-eight have been found fossil in Australia. Judging from these alone, it would seem that some authors have assigned too remote an age to the deposits. The new forms described were:—*Membranipora occultata; Monoporella capensis*, var. *dentata*, *M. waipukurensis; Micropora variperforata; Mucronella tricuspis*, vars. *waipukurensis* and *minima*, *M. firmata; Porina grandipora; Lepralia semiluna*, var. *simplex*, *L. bistata; Schizoporella cinctipora*, var. *personata*, *S. tuberosa*, var. *angustata; Cellepora decepta, Cellepora* sp.

Royal Microscopical Society, November 10.—Rev. Dr. Dallinger, F.R.S., President, in the chair.—A microscope, with case of apparatus and a cabinet of objects, bequeathed to the Society by the late Miss Tucker, was laid on the table.—Amongst the exhibits was a microscope for examining minute aquatic organisms under very high pressures; Leeuwenhoek's microscopes; objectives made of the new glass by Zeiss and by Powell, which were very highly spoken of by the President and others; and some gold-plated diatoms.—Mr. S. O. Ridley read a paper on the classification and spiculation of the monaxonid sponges of the *Challenger* Expedition; drawings and specimens illustrative of the various typical forms were shown.—Mr. A. Dendy also read a paper on the anatomy and histology of the monaxonid sponges of the *Challenger* Expedition, the subject being illustrated by drawings and specimens.—Dr. Crookshank read a paper on flagellated Protozoa in the blood of diseased and apparently healthy animals. He described a disease known in India as "Surra," occurring among horses, mules, and camels. A parasite was discovered in the blood of these by Dr. Evans, and was referred to Dr. Lewis for an opinion as to its nature, who concluded that it was not identical with, but closely allied to, the flagellated organisms which he had observed in Indian rats. Five years later an outbreak of the same disease occurred in British Burmah, and the report of an investigation was published by Veterinary Surgeon Steel, who observed the same parasite, but regarded it as closely allied to the Spirillum of relapsing fever in man, and named it *Spirochœta evansi*. This opinion was not accepted by Dr. Evans, who placed blood, stained preparations, and material for section cutting, in Dr. Crookshank's hands for further opinion. Dr. Crookshank at once dispelled the idea of the parasite being a Spirillum, and gave a full account of his observations. These had led him to discover an anterior flagellum, a longitudinally-attached undulating membrane, and a posterior, acutely-pointed, rigid filament, from which characters he recognised that the parasite was a flagellated monad, probably absolutely identical with the parasite discovered by Mitrophanow in the blood of the carp, and named by him *Hœmatomonas carassii*. Dr. Crookshank consequently observed that the Surra parasite should rather be called *Hœmatomonas evansi* than *Spirochœta* as suggested by Steel. Lewis's observation with regard to the flagellated organisms in Indian rats led Dr. Crookshank to investigate the species obtainable in England, which resulted in his discovering flagellate parasites in 25 per cent. of apparently healthy rats from the London sewers. These organisms proved to be morphologically identical with the Surra parasite and the parasite described by Mitrophanow in the blood of the carp, and were also recognised by a photo-micrograph made by Lewis to be identical with the organism observed by him in Indian rats, though Lewis's description and figures presented material differences.

Entomological Society, December 1.—Robert McLachlan, F.R.S., President, in the chair.—Messrs. W. H. Miskin, R.E. Salwey, and F. W. Biddle, M.A., were elected Fellows.—Mr. Howard Vaughan exhibited a long series of *Gnophos obscurata*, comprising specimens from various parts of Ireland, North Wales, Yorkshire, Berwick-on-Tweed, the New Forest, Folkestone, Lewes, and the Surrey Hills. The object of the exhibition was to show the variation of the species in connection with the geological formations of the various localities from which the specimens were obtained.—Dr. Sharp showed a series of drawings of New Zealand Coleoptera, by Freiherr von Schlereth, which, though executed in pencil, were remarkable for their delicacy and accuracy.—Mr. R. Adkin exhibited specimens of *Cidaria reticulata*, recently bred by Mr. H. Murray, of Carnforth, from larvæ collected near Windermere, on *Impatiens noli-me-tangere*. Mr. Adkin said that, as the food-plant was extremely local, Mr. Murray had endeavoured to get the larvæ to feed on some other species of balsam, including the large garden species usually known as Canadian balsam, but that he had not succeeded in doing so.—Mr. Billups exhibited a number of living specimens of *Aleurodes vaporariorum*, obtained from a greenhouse at Snaresbrook, where they had caused great havoc amongst tomato-plants (*Lycopersicum esculentum*). He remarked that the species had been first figured and described by Prof. Westwood in the *Gardener's Chronicle*, 1856.—Mr. Poulton exhibited the blood of a larva of *Smerinthus tiliæ*, and demonstrated, by means of a micro-spectroscope, the existence of chlorophyll therein.—Mr. G. T. Porritt exhibited forms of *Cidaria suffumata* from Huddersfield, and a series of small bilberry-fed *Hypsipetes elutata* from the Yorkshire moors, showing green, red-brown, and black forms.—Mr. S. Stevens exhibited forms of *Camptogramma bilineata* and *Emmelesia albulata* from the Shetland Isles, and a variety of *Chelonia caja* from Norwich.—Mr. H. Goss read a letter from the Administrator-General of British Guiana, on the subject of the urticating properties possessed by the larvæ and pupæ of certain species of Lepidoptera collected in Demerara.—Mr. McLachlan read a note concerning certain *Nemopteridæ*.—Miss E. A. Ormerod communicated a paper on the occurrence of the Hessian Fly (*Cecidomyia destructor*) in Great Britain. It appeared from this paper that there could be no longer any doubt as to the occurrence of the insect in this country, specimens obtained in Hertfordshire having been submitted to, and identified by, Prof. Westwood, and by Mr. W. Saunders, of Ontario. Prof. Westwood said the specimens agreed exactly with Austrian specimens in his possession, sent to him some years ago by M. Léfèvre, who had received them from the late Dr. Hammerschmidt, of Vienna. A discussion followed, in which the President, Mr. C. O. Waterhouse, Mr. Theodore Wood, and others took part.

Victoria (Philosophical) Institute, December 6.—A paper was read by the Rev. S. D. Peet on the religious beliefs and traditions of the aborigines of North America, which was followed by a discussion.

EDINBURGH

Royal Society, December 6.—Mr. J. Murray, Ph.D., in the chair.—The chairman gave an opening address. Among other points, he referred to the almost total absence of recognition by Government of scientific research in Scotland. The Ben Nevis Observatory, for example, instead of receiving support from Government, is, on the contrary, a source of considerable revenue to it.—The Hon. Lord Maclaren communicated astronomical tables for facilitating the computation of differential refraction for latitudes 56° and 57° 30′.—Prof. Tait communicated the second part of his paper on the foundations of the kinetic theory of gases. In this part he treats of gaseous viscosity, and conduction and diffusion of heat in gases. In his investigations he takes account of the fact that the mean free path of swift-moving particles is greater than that of slow-moving particles. This point has been wrongly introduced by all previous investigators.—Mr. R. T. Omond communicated an account of a fog-bow observed on Ben Nevis, October 22, 1886. He communicated also an account of experiments on the temperature at different heights above ground at Ben Nevis Observatory. He hopes to repeat them under more favourable atmospheric conditions, and also when the ground is covered with snow.

Mathematical Society, December 10.—Mr. George Thom, President, in the chair.—Mr. R. E. Allardice read a paper on the equiangular and the equilateral polygon; and Mr. J. S. Mackay communicated a solution and discussion, by M. Paul Aubert, of a geometrical problem.

PARIS

Academy of Sciences, December 13.—M. Jurien de la Gravière, President, in the chair.—Glycose, glycogen, and glycogeny in connection with the production of heat and mechanical force in the animal economy, by M. A. Chauveau. In this third and last contribution on the subject, an attempt is made to determine absolutely the extent to which the combustion of glycose co-operates in the development of animal heat and energy. The part played by the liver in these phenomena is specially studied, and it is shown generally that the glycose supplied by the liver to the blood constitutes the principal aliment of organic combustions, whence are derived animal heat and muscular energy.—Note on an epidemic of typhoid fever which prevailed at Pierrefonds during last August and September, by M. P. Brouardel. This outbreak is clearly traced to the polluted sources whence was derived the water consumed by the inhabitants of the Pierrefonds district.—On the formation of Bilobites during the present epoch, by M. Ed. Bureau. In order to determine the true character of the doubtful fossil organisms still by many naturalists classed with the Algæ, the author has carefully studied the traces of all kinds observed especially at points on the coast of Brittany, where extensive tracts are exposed at low water. Impressions have been taken of marks due to animals, yet exactly resembling the forms occurring in Secondary and even Primary formations often described and figured as belonging to the vegetable kingdom.—On the means of reducing momentary accelerations of velocity in machines fitted with regulating gear acting indirectly, by MM. A. Bérard and H. Léauté. The object of this memoir is to supply trustworthy governors, applicable especially to machinery used in the manufacture of gunpowder. For the apparatus here described, it is claimed that, while giving the required uniformity of action, it checks all abnormal increase of speed, so dangerous in this industry.—Observations of Finlay's comet (1886), made at the 0·38 m. equatorial of the Bordeaux Observatory, by M. F. Courty. The tabulated results of these observations include the mean position of the stars taken as points of comparison borrowed from Schœnfeld's Catalogue, published in the eighth volume of the "Bonn Observations," 1886.—A practical demonstration of the existence of diurnal nutation, by M. Folie. The remarkable agreement of the results here recorded, deduced from observations made at various points of latitude and longitude, is considered sufficient to prove the existence of the diurnal nutation of the terrestrial axis, and to determine its constant at about 0·2″.—On certain problems of isochronism, by M. G. Fouret.—On a theorem relating to the permanent movement and flow of fluids, by M. Hugoniot. The curious relation which is shown to exist between the permanent movement of fluids and that of the propagation of sound is here investigated.—On the coefficient of explosion for a perfect gas, by M. Félix Lucas. Various arguments are advanced to show that this coefficient is 1·40, not 1·41, the number generally adopted. — On the coefficient of pressure for thermometers, and on the compressibility of liquids, by M. Ch. Ed. Guillaume. The probable coefficient resulting from M. Descamps' experiments is shown to approximate very closely to that of Regnault, and the coefficients of compressibility must be corrected accordingly.—On the nature of electric actions in an insulating medium, by M. A. Vaschy. Assuming that the reciprocal actions of two electrified bodies are exercised through the intermediary of the intervening medium, and not directly at a distance, the author endeavours here to determine the part played by this medium in the transmission of the electrostatic actions. The medium itself is regarded as a combination of the ether and ponderable matter in relations to be subsequently determined.—Note on an absolute electro-dynamometer, by M. H. Pellat. By means of this instrument, which has been constructed by M. Carpentier, the intensity of a current may be determined directly in absolute value with an error less than 1/2000.—Note on steno-telegraphy, by M. G. A. Cassagnes. By this combination of mechanical stenography and telegraphy the operator is enabled to record and transmit along a single wire a considerable number of words instantaneously. Numerous experiments on the French lines have yielded the following results for a single wire: (1) 400 words a minute to a distance of 350 kilometres (with two fingerboards 24,000 words an hour); (2) 280 words a minute to a distance of 650 kilometres (with two boards 16,000 to 17,000 words an hour); (3) 200 words a minute to a distance of 900 kilometres (with one board 12,000 words an hour). Messages may even be forwarded simultaneously in both directions, and the system offers other advantages greatly accelerating and simplifying telegraphic work.—On a process of rock-erosion by the combined action of the sea and frost, by M. J. Thoulet. Certain results observed on the Newfoundland coast are attributed to the combined action of liquid and frozen water.—On some coloured reactions of arsenic, vanadic, molybdic, and arsenious acids, as well as of the oxides of antimony and bismuth, by M. Lucien Lévy.—Thermic phenomena accompanying the precipitation of the bi-metallic phosphates and allied salts, by M. A. Joly. Here are studied the extremely complex relations of bicalcic, bibarytic, distrontianic, and other phosphates, bibarytic arseniates, and monobarytic hypophosphate.—Heat of neutralisation of glyceric and camphoric acids, by MM. H. Gal and E. Werner.—On the water-bearing apparatus of *Calophyllum*, by M. J. Vesque. A study of this highly specialised apparatus enables the author to classify the twenty-five known species of the genus *Calophyllum*.—Analysis of the Javanese mineral waters, by M. Stanislas Meunier. The specimens here examined were brought from the Kuripan district, near Boghor, and yielded 54·203 per cent. of chloride of calcium, 40·651 of chloride of magnesium, 2·860 of chloride of sodium, 1·104 of chloride of potassium, and 1·924 residue insoluble in water.—On a new locality containing the nummulitic formations of Biarritz, by M. de Folin.—On the importance and duration of the Pliocene period studied in connection with the Roussillon basin; fresh documents relating to the Pliocene mammiferous fauna of this district, by M. Ch. Depéret. In the discussion which followed the reading of this paper, both M. Gaudry and M. Hébert argued that the Pikermi and Léberon deposits should be referred, not to the Pliocene, but to the Upper Miocene epoch.—Note on the reptiles and fishes found in the caves of Mentone, by M. Emile Rivière.—On the storm of December 8, by M. Fron.—The Föhn and its cosmic origin, by M. Ch. V. Zenger. It is argued that this wind is a cyclonic movement of cosmic origin, allied to such phenomena as the aurora borealis, electric and magnetic storms, terrestrial currents, and the seismic waves which so often accompany violent tempests.

BOOKS AND PAMPHLETS RECEIVED

Crustacea and Spiders: F. A. A. Skuse (Sonnenschein).—The Queen's Jubilee Atlas of the British Empire: J. F. Williams (Philip).—A Concise History of England and the English People: Rev. Sir G. W. Cox (Hughes).—The Tea-Planter's Manual: T. C. Owen (Ferguson, Colombo).—Disease and Sin (Wyman).—Hours with a 3-inch Telescope: Capt. W. Noble (Longmans).—Proceedings of the Davenport Academy of Natural Sciences, vol. iv. (Davenport, Iowa).—Zeitschrift für wissenschaftliche Zoologie, Vierundvierzigster Band, Drittes Heft (Engelmann, Leipzig).—Differential Calculus: J. Edwards (Macmillan).—Proceedings of the American Philosophical Society, vol. xxiii. No. 123 (Philadelphia).—Report of the National Academy of Sciences, 1885 (Washington).—Bulletin of the U.S. Geological Survey, Nos. 27, 28, 29 (Washington).—Morphologisches Jahrbuch, 12 Band, 3 Heft: Prof. Gegenbaur (Engelmann, Leipzig).—Bulletin de la Société Impériale des Naturalistes de Moscou, No. 2, 1886 (Moscou).

THURSDAY, DECEMBER 30, 1886

BABINGTON'S "BIRDS OF SUFFOLK"

Catalogue of the Birds of Suffolk; with an Introduction and Remarks on their Distribution. By Churchill Babington, D.D., &c. Reprinted from the *Proceedings* of the Suffolk Institute of Archæology and Natural History. 8vo, pp. 281. Map and 7 Plates. (London: Van Voorst, 1884-86.)

NUMEROUS as have lately been contributions to local British ornithology, the treatment of the subject is very far from being exhausted, and Dr. Babington's book is extremely welcome as supplying a new catalogue of the birds of a county having so favourable a situation as Suffolk. For though wanting the extended sea-board of one neighbour, Norfolk, which meets the uninterrupted roll of the polar waves, and possessing an almost even coast-line, very unlike the irregular contour of its other neighbour, Essex, Suffolk yet contains the most easterly point of England in Lowestoft Ness, as it is still fondly called, though a "ness" is there as hard to recognise in these days as is the "bay" of its historic Solebay, a few miles further south. Suffolk also is not without its "broads"—at Fritton, Oulton, Benacre, and Easton—insignificant as they may be in comparison with those of the northern half of the ancient East Anglian kingdom. It also shares with Norfolk the great Breydon Water, and with Essex the wide mouth of the Stour, while it has for its own the estuaries of the Blythe, the Alde, the Debden, and the Orwell, by no means despicable, even if they are not equal in size to those of the Colne, the Blackwater, and the Crouch, that drain so much of Essex. Suffolk again has a natural feature, the like of which is not possessed by either of its neighbours:—

> "On Orfordness lies many a stone,
> But Dungeness has ten for one,"

says the old adage, and it is not until the south-eastern corner of Kent is reached that a similar "beach" is presented, and that one only to be surpassed by the Chesil Bank of Dorset. Highly cultivated, too, as now is almost every acre in Suffolk that will repay cultivation, there are still some wide tracts along its eastern border, and again towards its north-western extremity, which, if indeed they have ever been under the plough, have long since lapsed into an approach to their original condition, and are overgrown with heather and gorse, or form "brecks," kept, by the teeth of countless sheep and rabbits, in the state of the poet's "smooth-shaven green." The western limits of the county not only bound, but slope into, the great Fen district, that spreads for miles and miles in an almost level plain towards the Wash. The chief part of Suffolk has long been inclosed, presenting, in the absence of any but the most inconsiderable elevations, a very uniform appearance; and, were it not for its numerous woods—not many of which are really ancient—and plantations, would afford harbour to few but the commonest of birds. An indefinite district, the soil of which is of the stiffest clay, is colloquially named "High Suffolk"; but where it begins or ends, no one knows; and, for some mysterious reason, nobody will own to living in it. "High Suffolk" always begins in the next parish, or the next parish but one! A great contrast to these heavy lands is presented by the "breck" district already mentioned, where the chalk-formation comes nearly to the surface, and is only overlain by a few inches of the lightest sand — so light, indeed, that some places may be found as bare of vegetation as is a real desert—every particle of fertilising matter having been blown away by the wind after a spell of dry weather; and it will be remembered that in East Anglia the rainfall is less than in any other part of England. This district still retains, in at least one of its birds, in some of its insects, and in a few of its plants, indications of having been once—and that perhaps not so very long ago—a littoral, an arm of the sea having doubtless reached its low hills, and in after times retreating, having left these survivors who still hold their ground. But here we may say that we cannot for a moment subscribe to the opinion to which Dr. Babington gives currency (p. 123), though not saying whether he himself shares it, that the marine connexion was by "a broad estuary running from the South Suffolk coast between Bury St. Edmund's and Stowmarket through Thetford." So far as we are aware, there is no evidence in favour of such a violent supposition, and much against it. On the other hand, a very slight depression of the surface would once more bring the sea from the Wash up to Brandon, if not to Thetford.

We make no attempt to trace the deeper effects of geological formations and changes; but all these superficial characters, here so briefly sketched, combined with the geographical situation of the county, will serve to show why Suffolk should present a field of great interest to the ornithologist; its varied features offering suitable accommodation for many kinds of birds of diverse habits, and its eastward position a sanctuary where the wings of many a weary wanderer from afar may be folded at rest. There is the more need to urge the importance of these favourable circumstances, because they cannot be said to be too prominently laid before his readers by Dr. Babington, who perhaps through modesty, or perhaps through prudence (in which latter case he is certainly to be commended), abstains from setting forth the advantageous conditions of existence that the county of his adoption thus affords, albeit he devotes a few pages (258-268), which might well have been more, to the subject.

In computing the birds of a circumscribed area, it is always a difficult task to decide whether the adventitious strangers whom the accidents of travel may have driven upon its coast should be enumerated among its real inhabitants, for there is really much to be said on both sides of the question. At first sight it seems most absurd that, granting even there is no reasonable probability of its importation, the stray example of an exotic species, whose home may perhaps be in the further wastes of Northern Asia or the wilds of Arctic America, should be enrolled as a "British bird," because it has had the ill-luck to find its way hither and be killed—*secundum usum Anglicanum*—within the confines of the United Kingdom; but almost immemorial practice may be pleaded for this view of the case, and we are not minded to place on record a distinct decision against the claims of a local faunist on so delicate a question. However, the local faunist should recognise the fact that a long list is not necessarily "a strong list"—to use Dr. Babington's expression—and if space allowed us to go into details we should be inclined to strike off not a few species from his register. It is true that this would not materially alter his position, for a corresponding number would on the same ground have to be struck off the register of other counties. In reality, no one has ever doubted that the Suffolk roll is one of the highest to be found in England. Perhaps it would stand only second to that of Norfolk on the English record, for though both, so far as published lists go, are inferior to that of Yorkshire, we are persuaded that this last has been unduly swollen. We have a strong suspicion that a Kentish list would run any of them very hard; but we here speak without facts, for ornithologists have long been scarce in Kent, and no attempt at a Kentish list has been made for many a year. The comparison instituted by Dr. Babington between the ornithological wealth of Suffolk and certain other counties is in some measure fallacious,—the last list of Sussex birds, for example, dates from 1855 (not 1865 as he inadvertently states), while practically it was compiled in 1849, since which time a good many things have happened. Comparison with inland counties is of course misleading, and probably the well-known published catalogues for Cornwall, Somerset, Northumberland, and Durham, and for the Humber district, are alone those with which catalogues for Suffolk and Norfolk can be rightly compared; while the county last named, from the abundance of ornithological observers it has produced, is manifestly favoured in the race. One other thing may perhaps be mentioned in this connection, and that not so much for Dr. Babington as for authors of future "Avifaunas"; the ornithological richness of a district depends far more on the number of its real inhabitants than on the number of species which have occurred as stray visitors within its limits and only *bonâ fide* travellers. As regards large areas this is a truth so obvious that our remark may seem to be a platitude, but as regards small areas the consideration is too often overlooked.

Among all the English works on local ornithology with which we are acquainted, Dr. Babington's holds a peculiar place. Its contents are distinctly matters of fact, or of what passes for fact; in other words, it is a summary of records. No one would pretend to say that any book of this kind is, or could be, exhaustive; but the author has done his best to make his work so, and the infinite pains he has taken to be precise are present on every page—for every page bristles with references that have obviously cost him immense labour to collect, and his patient industry in culling them deserves the highest praise. On the other hand, this very precision may not unfrequently mislead the unwary. Unless the reader have a competent knowledge, elsewhere obtained, he may be apt to presume that the fact of such or such a species having been recorded as occurring or breeding at such or such a place and at such or such a time is an indication that it has not occurred or bred there at any other time. For the sake of those who are beginners, or ill-instructed in ornithology, and they ought to form a majority of those who use this book, it would have been better had the author uttered a warning against this kind of misconception, which in many cases is certain to follow from this concise method of citing previously recorded observations. Experts, of course, will not be taken in by it, but we think it may deceive others. Experts, however, unless they be accustomed to the way in which local floras are compiled, have some right to complain of the application of botanical methods to a fauna—for it is plain that the "Catalogue of the Birds of Suffolk" is planned on essentially the same principle as would have been a catalogue of the plants of the same county, and not according to any zoological precedent.

A few words are Dr. Babington's due on another matter. To most zoologists his name will be new, and yet he entered the field of biological literature nearly five-and-forty years ago! His ornithological appendix to Potter's "History and Antiquities of Charnwood Forest," published in 1842, was a respectable, not to say ambitious, performance for an undergraduate; and, while showing rudiments of the same scrupulosity as is seen in the present work, is equally removed from loquacity, though containing some information that the British ornithologist would not willingly let die. Both in conception and in execution it naturally has been surpassed by later publications, nor can it be regarded as the original precursor of the numerous local "Avifaunas" of Britain The primacy in this respect[1] belongs, we believe, to. one the author of which has lately died, and to his memory we take this occasion of offering a passing tribute. The "Ornithological Rambles in Sussex," to which was added a catalogue of the birds of that county, appeared in 1849, the work of Mr. Arthur Edward Knox, who died on September 23, 1886, having nearly completed his seventy-eighth year. Mention of this observant naturalist, agreeable author, and accomplished gentleman is all the more needed, since his death obtained scant, if any, notice in the newspapers of the day, though column after column in their broad sheets chronicled the career of a successful horse-jockey who expired not long after. Mr. Knox, it is true, never assumed the character of a man of science any more than that of a man of letters, yet his literary style was of the best, while few professed naturalists more thoroughly practised scientific methods of observation, and none could more fully appreciate scientific worth. His three works—that already named, his "Game-Birds and Wild Fowl," and his "Autumns on the Spey"—all of the kind that is usually called "popular," have some characteristics that at once distinguish them from so many others to which that epithet is commonly applied. They are always accurate, seldom trivial, and never vulgar.

To return, however, to Dr. Babington's little volume. Its value, notwithstanding some shortcomings to which we have referred, is great, and the recorded facts, with which, as already stated, it is crammed, are such as no "British" ornithologist can afford to neglect. As a final mark of attention, let us notice that Dr. Babington's scholarly instinct has inspired him with enough courage to be the first writer who has corrected an unhappy mistake made by Linnæus, and restored (pp. 200-203) the old

[1] Of course there are several other local lists of older date, from that of Markwick downwards, including "The Norfolk and Suffolk Birds" of Sheppard and Whitear; but these were published in journals (mostly in the Linnean *Transactions*), and we are here speaking of separate works the scope of which is ornithology alone.

spelling *Podicipes*, for the ungrammatical, senseless, and misleading *Podiceps*, thereby removing a reproach wh ic every literary man could successfully cast at a zoologist. *Exemplum sequendum!*

INTERMITTENT DOWNWARD FILTRATION

Ten Years' Experience (now Fourteen Years) in Works of Intermittent Downward Filtration. By T. Bailey-Denton. Second Edition. (London: E. and F. N. Spon, 1885.)

THE treatment of sewage by intermittent downward filtration on specially prepared areas of land is now generally recognised as the most efficient method for the purification of the sewage of towns. Mr. Bailey-Denton is one of the ablest exponents of this system, and one who has had large experience in its practical application. He is also well known as being the joint author, with Col. Jones, of a well-devised scheme for treating the sewage of the metropolis on Canvey Island at the mouth of the Thames—a scheme, however, which has not been received with any sort of approval by the Metropolitan Board of Works. The Royal Commission on Metropolitan Sewage Discharge considered very fully the merits and demerits of the system, and expressed their opinion—"(1) That the process has great scientific merit, and offers valuable practical advantages for the disposal of sewage in situations where broad irrigation is impracticable, and where land suitable for filtration can be obtained. (2) That, however, it appears desirable, when the area of land is considerably reduced, that the sewage should be previously treated by some efficient process for removing the sludge. (3) That an arrangement of this kind would be applicable to the metropolis. . . ." Broad irrigation was defined by the Royal Commission to mean "the distribution of sewage over a *large* surface of ordinary agricultural ground, having in view a maximum growth of vegetation (consistently with due purification) for the amount of sewage supplied," whereas filtration means "the concentration of sewage, at short intervals, on an area of specially chosen porous ground, as *small* as will absorb and cleanse it; not excluding vegetation, but making the produce of secondary importance." On a suitable soil—a sandy loam with a small proportion of gritty gravel to quicken percolation is the best—specially prepared by surface levelling and deep under-drainage, one acre is capable of effectually purifying the sewage—without any preliminary treatment—of 1000 people, provided that the sewage is free from any large proportion of trade or manufacturing refuse, and that storm and surface waters are kept out of the sewers. The obligation to treat storm waters, which come down in the sewers in times of heavy rain, is one of the greatest obstacles in the path of any system of sewage purification, and will continue to be until all towns are supplied with a dual system of drains and sewers. One inch of rain, thrown off 100 acres, equals 2,262,200 gallons; "and if," says Mr. Bailey-Denton, "one-tenth of this quantity suddenly reaches the outfall—say, in half an hour—no mode of treatment yet devised can deal with such a quantity without injury or defect." As a rule, at the present time, despite prospective penalties for river pollution, the mixed sewage and storm water is allowed to pass into the rivers without any sort of treatment. Mr. Bailey-Denton recommends that the storm overflow be connected with osier beds. "The beds are formed in horizontal areas which serve to *check* the rapidity of flow of suddenly discharged rainfall. This check causes the deposit of the floating solid matters in the furrows, while the flood-water rises and overflows the ridges and the osiers growing on them. These beds are not under-drained in any way; their simple purpose being to clarify those excess-waters which, without the check afforded by them, would be impetuously discharged, together with everything floating in them, into the natural streams of the watershed." Mr. Bailey-Denton does not think it necessary or even desirable, in most cases, to precipitate the sludge—the minute suspended particles, organic and inorganic, of sewage—by chemical processes or depositing tanks, before the sewage is applied to the filtration beds. He does not believe that the sludge, unless mixed with solid trade refuse, under proper treatment is capable of clogging the pores of the land or of injuring vegetation. He recommends the filtration beds to be laid out in ridges and furrows—the sewage only flowing into the latter, and not being allowed to flood the ridges on which plants and vegetables are growing. The plants cannot then be injured by the deposit of the solid ingredients of the sewage on their stalks and leaves. "As soon as the deposit of sludge on the sides of the furrows is sufficient to prevent infiltration in any great degree, the sewage is withheld from the areas so affected. The sludge is then allowed to dry (partially) in the furrows, and when in a fit condition it is lifted and dug into the ridges,—as can be seen practised at Gennevilliers (Paris). The slimy matter which had appeared so considerable, and which puddled the bottom of the furrows, when in a wet state, shrinks to a skin of very insignificant thickness when dry, and is readily broken up and mixed with the soil." Still Mr. Bailey-Denton admits that the extraction of the sludge has one great advantage, viz. that "the same land will filter double the quantity of clarified sewage liquid that it would cleanse sewage of which the finer particles have not been removed;" a very important point to towns where the area of land at disposal for sewage purposes is strictly limited.

The intermittency of the application of the sewage to the filter beds is a *sine quâ non.* Each bed should have 18 hours' rest out of the 24, to allow air to follow the sewage as it percolates through the pores of the land, thereby renewing the oxidising properties of the soil—properties largely dependent, no doubt, on the life and growth of certain Bacterial organisms resident in the superficial layers of the soil, which have been shown by Warington and other observers to be the principal agents in the nitrification and purification of the nitrogenous organic matters of sewage. The assimilative power of growing plants is doubtless also a great aid in the purification of sewage, and the plan of ridges and furrows adopted by Mr. Bailey-Denton, in enabling him to raise large crops on filtration areas, has taken away from the system the reproach that it was utterly unremunerative. There can, however, be no doubt that it is in combination with surface or broad irrigation that intermittent filtration is likely to have its most useful application. In a valuable chapter on sewage farming, Mr. Bailey-Denton points out that whatever the estimated value of sewage may be —8*s.* 4*d.* per annum per head of the inhabitants of water-closet towns, or 1⅗*d.* per ton with a dilution of 61 tons—it is actually reduced to the sewage farmer by attendant drawbacks to the present mode of application to much less than ¼*d.* per ton. The sewage must be applied to the land whether it is wanted or not, and may, under such circumstances, be the cause of mischief to crops rather than of benefit. It has been assumed that by surface irrigation one acre is capable of purifying the sewage of 100 persons; but what farmer, Mr. Bailey-Denton very pertinently remarks, would give even a farthing per ton for the obligation to apply in a year 6100 tons of liquid to an acre—equivalent to a superincumbent depth of 5 feet, or 2½ times the average rainfall—though he would gladly give a larger price per ton if he could have what he wanted, just at such times as he wanted it? "All experiences tend to prove that the obligation to 'get rid' of a large quantity of sewage under all circumstances and conditions, at night as well as day, on Sundays as well as week-days, on cropped lands as well as fallows, and at all stages of growth, from seed-time to harvest, puts it beyond the reach of man to gain any real profit from it." Many of the ordinary farm crops, as cereals, pulses, potatoes, and turnips, are injured by the application of sewage. Rye-grass, cabbages, mangolds, carrots, parsnips, and perhaps onions, are the plants that thrive best under sewage (it is said to be impossible to overdose rye-grass with sewage); but these are crops that may very readily be produced in larger quantities than there are markets for.

The great drawback, alluded to above, can be overcome by every sewage farm having specially prepared filtration areas, capable of purifying the whole sewage, when not wanted on the general surface of the farm, and leaving it within the power of the occupier to draw such quantities, at such times as he requires them, as dressings for his crops. Under such arrangements sewage farming may be expected—as it has been found by Mr. Bailey-Denton at Malvern and elsewhere—to be remunerative to the farmer and satisfactory to the town authorities. The cost of laying out the land for intermittent filtration is high—from 30*l.* to 150*l.* per acre in difficult cases, according to Mr. Bailey-Denton's estimate—but not sufficiently high in any way to counteract the immense advantages which the possession of such filtration areas confers.

A MEDICAL INDEX-CATALOGUE

Index-Catalogue of the Library of the Surgeon-General's Office, U.S. Army. Vol. VII. Insignarès-Leghorn, pp. [100] and 959. (Washington: Government Printing Offices, 1886.)

THE masterly way in which Mr. J. S. Billings is conducting this Index-Catalogue, and publishing punctually year by year these large volumes of about a thousand closely-packed pages, is a matter worth the attention not only of all interested in medicine and surgery, but also of all interested in modern libraries and modern journalistic literature. For the Library of the Office of General Robert Murray, Surgeon-General of the U.S. Army, though only founded in 1830, is now one of the largest collections of medical literature in the world, larger possibly than that of the British Museum, of the Bibliothèque Nationale of Paris, or the collections of Berlin or Vienna, and it contains some manuscripts, notably a letter of Edward Jenner's, which the English librarians would be glad to have. Its catalogue is certainly much more complete, as far as it has been published, in spite of the method of execution having been much more difficult. For these seven volumes that have been hitherto published contain more than 254,000 references to articles or essays in journals and periodicals of all kinds and in all languages, arranged under the subjects to which they refer. The French and German pleasure in framing appended bibliographies on the subjects of some monographs which they publish has never given them courage enough to face such a Herculean task. The number of periodicals which either have been or are being taken in by the Library has risen since last year, when vol. vi. was published, from 3005 to 3270, and extends through a wide geographical range, from the *Norsk Magazin* of Christiania, to the *Klin-le I-letzu* (the *Modern Medical News*) of Yedo; and in wide range of interest from the *Revue des deux Mondes*, to the *Dental Luminary* of Macon, Ga., U.S. The learned compilers of the Index-Catalogue are good enough always to translate the Japanese titles when they print them in English letters; indeed they sometimes go further, and, avoiding the difficulty of even transliterating them, give us merely the title in English, with a warning note that the original title is Japanese. Magyar is also as a rule, though not by any means always, translated; Polish sometimes, Russian only occasionally. The whole method of the book is so perfectly orderly and symmetrical, that it makes us wonder whether this want of rule in translation is one of the trifling points in which the individualism of Mr. Billings' assistants has crept in; for we cannot see that the translated titles are in any way more difficult than the untranslated.

Under the subject-headings come the great masses of quotation of the titles of articles in periodical literature which make the Catalogue so unique. If we turn to the name of an author who writes both books and papers in journals, &c., we shall not find entered under it anything but his separately published works; though, probably, all of those down to his smallest reprint from some Society's *Transactions*, and with these, in smaller type, a reference to other books to which he has contributed or which he has translated; and, if he is dead, a reference, probably, to some biography of him, and some portrait; but, beyond this, none of his contributions to journals or *Transactions*. Nevertheless, under the subject-title of any such contribution, whether it be Jaundice, Jealousy, or Jequirity, will be found a reference to his article if it was signed, and his name, in bold type, clearly standing out among the mass of contributors to that branch of knowledge. It would have been possible, of course, to print such references twice over—once under the heading of the author, and again under the subject-title; but we can hardly wonder that that has not been done, as it would have added some five or six thousand pages to a series of volumes already in danger of being overweighted, and, also, it would have supplied information which is of more importance to the biographer than to medical science.

Of the subject-titles in this volume, the largest is Labor, under which, in 150 pages, a very complete library is catalogued of some 1500 books and 10,000 articles, well arranged under many headings. Under Kidney, the student will probably be content to find references to about 400 books and 2500 articles.

It is easy to show the vast extent of the work attempted and executed; that there are absolutely no inaccuracies in the result is hardly possible, difficult as it may be to find them. The references in this volume certainly stand many tests, and most of those who have made frequent use of the previous six volumes in practical work have acquired a confidence in their accuracy which is very rare in dealing with such an immense mass of varied languages and types and abbreviations so thickly interspersed with figures.

Both the Library and the Index-Catalogue are brought fully up to date. The volume is presented to the Surgeon-General of the U.S. Army in a letter of preface dated June 1, 1886, and it contains the books and periodical references practically complete up to the end of 1885. If any comparatively modern subject is examined, *e.g.* kairine, we find nothing said or known of it before 1882, and yet 120 references, taking us over all the published literature of the subject, down to the end of 1885.

This seventh volume includes the entries from Insignarès to Leghorn. It is likely to be the middle volume of this encyclopædic work; and certainly if Mr. Billings is able to publish his last and concluding volume in 1892 no one who has any interest in the progress of knowledge will hesitate to congratulate him and his colleagues even more heartily, if it be possible, than at present. A. T. MYERS

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Sounding a Crater, Fusion-Points, Pyrometers, and Seismometers

THE account given by Prof. John Milne of his ascents and attempts at sounding the crater of Asama Yama is exceedingly interesting, and I can thoroughly sympathise with him in the difficulties he encountered, having been exposed to them on many occasions, and not always coming off so victoriously. He and Mr. Dun, however, have been forestalled by the late Robert Mallet. When I came to Naples some eight years since, I found in one of the store-rooms of the geological department of the Naples University a quantity of apparatus which I soon made out the use of.

It appears that Mallet had this apparatus made especially for the purpose of measuring the temperature and studying the gases and the lava itself within the mouth of the volcano Vesuvius. On his arrival in Naples the state of the mountain did not permit of the experiments being carried on, and the whole of the materials were left in charge of Prof. Guiscardi, who could give no other information than the above. By carefully studying the apparatus I was soon able to understand Mallet's intentions and the mechanism he intended to employ. There are two drums of small wire cable—one for traversing the crater to hold a pulley over the "*bocca*," and the other for letting down the weight and crucible. The crucible is of cast iron with a bayonet-jointed cover, and is, no doubt, intended to contain substances of different fusibilities. The apparatus is, however, an improvement on that used in Japan, in that the sounding-rope is insulated and there is an electrical bell and battery so arranged that when the crucible enters the lava it makes an earth-contact and rings the bell. There are other pieces of apparatus that I could not get at, but I think they are intended for chemical researches.

From these facts it will be seen that Prof. J. Milne has been forestalled as far as the method is concerned, but no experiments were ever carried out, either by Mallet on account of failing health, or by those in whose hands the apparatus fell. I made application to be allowed to use the apparatus, but for various reasons was unable to.

Before leaving this subject, may I appeal to your readers for a list of substances the fusion-point of which is known, and all of which would be above a dull red heat? I should like to have as complete a series as possible, so as to obtain results confined within narrow limits. Also any suggestions as to the best form of pyrometer that might be forced into and held in a stream of flowing lava, and that would not be injured by the breaking off of the rocky crust on its removal.

May I be permitted to make a few observations on the question lately raised about the authorship of certain seismographs? Not long since I described in your pages certain instruments that I considered as likely to be useful in such violent earthquakes as shake Ischia from time to time. With the exception of two, no claim was made to originality of principle, and yet I received through your pages a severe scolding from Prof. Ewing. Now if we really go into the literature of the subject we shall find the horizontal pendulum is not the invention of Prof. Ewing, but his present form of seismograph is one of the best applications of such a contrivance for measuring the horizontal component of an earth-wave, and I think he is justified in calling it *his seismograph* in so far as the present model goes. If we did not allow so much, no man using a vertical pendulum, however well contrived and modified, could call such *his*. At any rate I shall leave Prof. Milne, Prof. Ewing, and Mr. Gray to fight their own battle, but Prof. Ewing has fallen into the very same error of which he not long since accused me.

Naples, December 20 H. J. JOHNSTON-LAVIS

The Recent Earthquakes

MAY I ask to be allowed to call attention to some points in relation to the two earthquakes mentioned in your issues of December 9, p. 127 ("Volcanic Eruption in Níua-Fu, Friendly Islands"), and December 16, p. 157 ("Earthquake at Sea"). As regards the first, it is stated that "The whole island has been in a disturbed state for some three months and a half, the dates of the principal disturbances coinciding remarkably with those which are going on in other parts of the world—earthquakes on June 8 and 11, which, I think, are the dates of the first New Zealand outbreaks. . . . This is, of course, not wonderful; but the final catastrophe here took place on August 31, which, we understand, was the exact date of the recent American earthquake. It was preceded for twenty-four hours by earthquakes, and went on for ten days."

Assuming the synchronism of the Tonga eruption and earthquakes with those of the North Island of New Zealand, there is this very interesting relation between the two localities, that they both lie very near to a great circle which I may designate as the "West Coast of Africa Great Circle." This passes through, or near, the following points:—

Cape of Good Hope to St. Helena Bay; mouth of River Orange; Walfish Bay; Cape Martha; Cape Lopez Gonzalez; Bonny River; Algerian coast, near Nemours; south-east coast of Spain, near Almanzora; north coast of Spain (3° 25′ W. long.); west coast of Ireland (Loop Head); southern point of Iceland (near Westmanna Island); north-west point of Iceland; Greenland, Cape York; Melville Island (south coast and point of); Bering Island; Cape Dalhousie and coast-line of Liverpool Bay; Alaska, Montagu Island; Tonga Island (half a degree to west of Tonga Tabu); New Zealand, north-east point of North Island; passes between Adelie Land and South Victoria Land; Enderby's Land. It may be remarked that several of these localities are noted for disturbances both volcanic and seismic.

As regards the "earthquake at sea" mentioned in your number of the 16th inst., the position where it was felt is given as N. lat. 19° 21′, and W. long. 64° 22′; this gives a point about 93 miles north-east of Porto Rico. The interest in this case lies in the fact that the antipodal point corresponding, being S. lat. 19° 21′ and E. long. 115° 38′, lies about 100 miles north by east of Barrow Island, off the west coast of Australia. It is further interesting to note that the line which joins this point with the southern point of Barrow Island fairly represents the direction of the coast-line at this point, and leads to the presumption of the existence of main lines of faulting there having that direction. To this relation of antipodean points in connection with earthquakes I have already had occasion to call attention. J. P. O'REILLY

Royal College of Science, Dublin, December 22

Barnard's Comet

THIS comet has been observed here with the 7½-inch refractor, with power 50, than which no higher power could be used with advantage.

On December 19, at 18h., it appeared as bright as a 2nd magnitude star similarly situated; the nebulous head was about 10′ in diameter, with central condensation of perhaps half a minute. The "position" of the principal tail was estimated to be 0°: it remains of a parallel breadth throughout, and does not increase in breadth as it recedes from the head of the comet; this constant breadth is equal to the diameter of the nebulous head, that is to say, 10′. By sweeping, this tail may be traced to a distance of some 10° from the head.

The secondary tail is inclined at an angle of between 30° and 40° to the principal one, and fades away rapidly at a distance of perhaps 1° from the head; it is well defined on the preceding side, but on the following side it melts away into a nebulous mass connecting it with the principal tail for some distance from the head.

On the 27th, at 19h., the comet was decidedly less bright than on the 19th, but the same general description applies.

The "positions" of the two tails were measured, and were: the principal tail, 15°·5; the secondary, 338°; the included angle, 37°·5 ± 0°·5. The secondary tail did not appear as well defined, on the following side, as on the 19th.

Finlay's comet presents no visible feature of interest.

WENTWORTH ERCK

Shankill, co. Dublin, December 28

Electricity and Clocks

IN the absence of any details, apparently Mr. Wilson's simplest plan would be to insulate the hammer and bell of his "small striking clock," and arrange that a galvanic current should pass through both, when they come in contact by the act of striking: this current of course to be directed to a large electro-magnet, to raise the hammer for striking on his bigger bell. Should the striking of Mr. Wilson's smaller clock be on a gong with a leather-beaked hammer, a separate attachment must be made for contact. HENRY DENT GARDNER

Lee, S.E., December 26

P.S.—If a longer contact be desired, the hammer whilst at rest should repose upon a weak spring, and be kept away from a banking; when the hammer rises, contact will ensue between the spring and banking, and last until the hammer falls again.—H. D. G.

Seismometry

THERE are one or two points in Prof. Ewing's letter on the above subject in the last number of NATURE which seem to call for a few words of reply.

(1) As to the alleged inconsistency between what I wrote in 1881 and what I wrote in my la t letter. The remark quoted referred to a light pivoted frame carrying at its centre of percussion, relatively to the axis through its pivot, a pivoted mass. There was no "if need be" about this mass: it was an essential part of the system. I believe the remark I then made was perfectly correct and in no way inconsistent with my remarks in 1886.

(2) As to the vertical-motion instrument, the lever with spring joint used at Comrie in 1842 does not at all resemble the rigid lever working on knife edges and supported by springs as introduced by me and used by Prof. Ewing. On the question of compensating the lever by the addition of negative stability, I have nothing to add to what I stated in my last letter.

(3) As to the publication referred to by Prof. Ewing, the memoir printed by the Tokio University is probably, from the circumstances of its publication, hardly known to anybody. The "Encyclopædia Britannica" article is not, in my opinion, a fair account of what has been done in seismometry.

7, Broomhill Avenue, Partick, December 27

The Recent Weather

AT Cardross, half-way between Dumbarton and Helensburgh on the Clyde, at about 25 feet above sea-level, in an outer lobby with a temperature of say 45° to 50° F. at 9 a.m. on Wednesday, the 8th inst., the mercurial barometer stood at 27·51 inches, which, with reduction of say 0·02 added for elevation, and say 0·03 subtracted for temperature, would make it 27·50 inches. On January 26, 1884, it stood at 27·39 inches, which with like reductions would give 27·38 inches. These are nearly as low as those you refer to in your number for last week.

Cardross, Dumbarton, December 23 R. B. W.

OBSERVATIONS OF NEBULÆ AT ARCETRI[1]

M. TEMPEL observes under difficulties. The Arcetri Observatory possesses, it is true, two fine refractors by Amici, one of 11, the other of 9⅓ inches aperture; but neither is, properly speaking, available for astronomical use. The smaller is rudely set up on an open and uneven terrace, exposed to every gust of wind, and, at the most, serves to display the wonders of the heavens to curious visitors. Amici I. is duly ensconced in a revolving dome, but clockwork motion is wanting; the circles, both of declination and right ascension, are (strange as it may seem) *undivided;* and when the necessarily somewhat unwieldy instrument is, with infinite pains and without so much as the aid of a handle, pointed towards the object sought, there is actually no means of clamping it in the position so laboriously arrived at! That M. Tempel, under circumstances so discouraging to him and disgraceful to the responsible authorities, should have executed a number of valuable drawings of nebulæ, should have re-observed many such objects neglected, or even believed to have disappeared, since the elder Herschel's time, besides discovering a good proportion of new ones, gives astonishing proof of his keenness, zeal, and accuracy. All the more, nevertheless, there is reason to regret that qualities so rare should be employed at such cruel disadvantage for want of the judicious expenditure of a couple of thousand francs.

The paper before us is accompanied by reproductions of two admirable drawings by the author, one of the Orion, the other of the "Crab" nebula (Messier I.). The latter is of especial interest, as disclosing a feature unnoticed by any previous observer. This is a dark cleft right through the central condensation, dividing it along the major axis into two spindle-shaped nebulæ. Incipient fission would seem to be indicated. On the same plate with his own, M. Tempel has engraved five earlier drawings of the object, by J. Herschel, D'Arrest, Lassell, Secchi, and Lord Rosse. The comparison is instructive, if somewhat disheartening; for, assuredly, no two of the six confronted delineations could be supposed, on an unprejudiced inspection, to have been inspired by one original. Yet the nature of that original sufficiently explains the discrepancies. The apparent form of nebulæ depends upon almost evanescent gradations of diffused faint light, and differs, for each individual eye, with its sensitiveness to them. And since personal equation, as regards such gradations, is shown by many proofs to be enormously large, a vast amount of detailed variation in the representation of the objects exhibiting them becomes intelligible. It is, then, a circumstance of pecu-

[1] "Ueber Nebelflecken. Nach Beobachtungen angestellt in den Jahren 1876-79 auf der Königl. Sternwarte zu Arcetri bei Florenz." Von Wilhelm Tempel. Abhandlungen der Königl. Böhm. Gesellschaft der Wissenschaften. VII. Folge, 1 Band. (Prag, 1885.)

liarly good omen for progress in the study of nebulæ that a mode of record at once so fluctuating and so laborious as that of hand-drawing should be replaced (as it will no doubt soon wholly be) by automatic impressions which, with some points of inferiority, at least leave no room for "individualism."

M. Tempel's description of the Merope nebula (discovered by himself in 1859), and his remarks on the great elliptical mass in the girdle of Andromeda, derive particular interest from recent events. His observational faculty, and the high quality of his telescope, are illustrated in the disclosure to him, by Amici I., of nearly 900 stars in the Pleiades, all of them comprised within the field of view of a 4-inch Steinheil bearing a magnifying-power of 24. With the former instrument he detected independently on September 30, 1875, a few days before reading Bond's description of them, the strange obscure channels in the Andromeda nebula; and has since with some difficulty made out similar markings in some small nebulæ of the same class. They would accordingly appear to be a more or less characteristic feature of "oval" nebulæ, and might perhaps be assimilated to the symptoms of partial duplication in Messier I.

In respect to the nature of nebulæ, our author's experience leads him decidedly to adopt the view of their close connection with stars. He shows, indeed, for spectroscopic evidence a disregard that is neither philosophic nor just; yet his contention that *purely gaseous* nebulæ do not exist, is probably well founded. No aggregation of celestial mist, at any rate, has ever been observed by him in which his 11-inch failed to reveal the pricking light of minute stars, marking some knot or nucleus, and thereby evincing structural relations of a most intimate kind.

THE MATHEMATICAL TRIPOS[1]

III.

WHEN the interval between the earlier portion of the examination and Part III. had been extended to a year, it became evident that some substantial relief must be afforded to the examiners. By the existing regulations a person who accepted the office of Moderator would have to take part in the examination in three consecutive years, and in his second year of office he would have to examine the candidates of one year in Part III. simultaneously with those of the year below in Parts I. and II. This led to the consideration of the whole question of the appointment of examiners. The two Moderators in each year are nominated by two colleges, according to a prescribed cycle of fifty years. This nomination by colleges, though theoretically not very defensible, had worked very fairly so long as the examination only included subjects with which any high wrangler might be expected to be acquainted; but it was clearly unsuitable for Part III. In any case the nomination of the four examiners by four independent bodies might easily bring about the result that among the various subjects included there would be some which had not been made the object of special study by any of the examiners: indeed there was nothing to prevent the four examiners being all pure mathematicians or all physicists. Accordingly, with a unanimity almost unique in matters relating to the Tripos, the Board recommended in a Report dated June 15, 1885, that the examiners for Part III. should be quite distinct from those for Parts I. and II., and that all four should be nominated by the Board. It was also proposed that they should hold office for only one year. This Report was sanctioned by the Senate on October 29, 1886. In future, therefore, the Moderators will not take part in the highest portion of the examination. The appointment of Moderators dates from 1680. Previously the Proctors had themselves presided in the schools, but in that year the duty of conducting the disputations was transferred to the Moderators, who were specially appointed to perform this office. The Moderators have always been, and still remain, high University officers, ranking next to the Proctors.[1] Not only were they the earliest examiners in the University, but it is to them that we owe the origin of the examination system. Their severance from a portion—and that the highest portion—of the examination is therefore a notable event in the history of the Tripos. Neither the Board nor the University would have agreed lightly to such a break in the traditions of the Senate House examination, had it been possible to retain the Moderators as examiners for the final part without altering the system of nomination by colleges. The complete separation of Part III. from the earlier parts of the examination was, however, inevitable. Many members of the University who would discharge most admirably the duty of examining for Parts I. and II. would shrink from Part III.; and the professors and specialists who were best fitted to examine in Part III. would generally be reluctant to undertake the heavy burden of examining all the candidates for Parts I. and II., especially in two consecutive years.

Thus, by the irresistible pressure of events, it has come to pass, in the last few years, that not only the titles of wranglers, senior optimes, and junior optimes have lost their old significance and refer only to the earlier examination, but that even the more ancient title and office of Moderator has undergone a similar restriction. The final part of the examination has indeed made rapid progress: within three years of its first coming into existence it has emancipated itself from union with the earlier parts, and become an independent examination.

Besides these important innovations, the Senate sanctioned at the same time a slight change in the nomenclature of the Tripos, the earlier portion of the examination, previously called Parts I. and II., upon which the list in order of merit depended, being designated Part I., and Part III. being henceforth designated Part II. This change was made in order to bring the nomenclature of the Mathematical Tripos into harmony with that of the Classical and other divided Triposes.

As soon as Part II., to adopt its new name, became an independent examination, the Board directed its attention to the schedule of subjects relating to it. The existing schedule contained only those subjects which had been included in the schedule which came into operation in 1873, when the results of the whole examination were still expressed by one final list, arranged in order of merit. Now that Part II. was a separate examination, and that there was no order of merit, the reasons for the limitation of the subjects had been entirely removed. Although the theory of elliptic functions, which dates only from the publication of Jacobi's "Fundamenta Nova" in 1829, was included, the theory of numbers, which had its origin in Gauss's "Disquisitiones Arithmeticæ" of 1801, was still excluded. Abelian functions, the theory of functions of a complex variable, projective geometry, and quaternions were not formally included by name, and questions on these subjects could only be set, if at all, by straining the meaning of the title of some other subject. Besides the total exclusion of certain branches of pure mathematics, a further reason for revising the existing schedule was afforded by the fact that the four groups A, B, C, D were very unequal both in magnitude and popularity among the students. According to the existing regulations the four groups had to be equally represented by questions,

[1] Address delivered before the London Mathematical Society by the President, Mr. J. W. L. Glaisher, M.A., F.R.S., on vacating the chair, November 11, 1886. Continued from p. 157.

[1] It is still the custom for the list of wranglers, senior optimes, and junior optimes to be shown to the senior Proctor on the evening of the day before it is read in the Senate House. This is doubtless a relic of the fact that the Moderators were originally the substitutes of the Proctors. It has been already mentioned that the Proctors, as well as the Vice-Chancellor, used to have the right to insert a certain number of names where they pleased in the Tripos list.

and this led to a great waste of examining power, many questions having to be constructed each year upon subjects which none of the candidates had studied. The Board accordingly formed a schedule in which all the subjects of pure and applied mathematics were included —none being intentionally omitted. These were divided into eight divisions, the first four relating to pure mathematics, and the last four to applied mathematics. To avoid the waste of questions that would ensue from the examiners having to represent all the subjects in the papers in each year, they proposed that before the first day of December preceding the examination the names of the candidates and of the divisions and subjects in which they desired to be examined should be forwarded to the Registrary of the University. The examiners would thus be made acquainted with the subjects which the candidates had studied, and would be able to frame their questions accordingly. Changes were also proposed with respect to the candidates who were admissible, and to the form of the final list. By the existing regulations only wranglers were allowed to present themselves for examination in Part II., and the list was arranged in three divisions; there was no separation into *classes*, because, as only wranglers were admissible, it was considered that all the candidates were first-class men from the beginning. The new proposals were, that the restriction which admits only wranglers should be removed, and that the candidates should be divided into three classes, each class being subdivided into as many divisions as the examiners in each year thought proper. In previous schemes the endeavour of the Board had been to frame regulations that would tempt the students to specialise their reading. A few years had made so great a difference that, with a view to prevent undue specialisation, the Board now inserted a regulation to the effect that proficiency in subjects taken from more than one of the divisions should be requisite in order that a candidate might be placed in the first class.

The Report containing these proposals was confirmed by the Senate on May 27, and it is noteworthy that both this Report and its predecessor, in which the nomination of examiners was placed in the hands of the Board, were sanctioned without opposition of any kind. The latter of these Reports also made a few minor changes, the most important of which was the omission of the problem paper which had been still retained, from the old five days, in the scheme of 1882.[1] The examination in Part II. had assumed such a character, that the kind of questions to which one would usually apply the name of problems was no longer in keeping with the contents of the other papers.[2]

Under the new scheme, in which all the examiners were to be appointed by the Board with special reference to their collective fitness for conducting the examination in Part II., there was no further need for an Additional Examiner, and this office was, accordingly, discontinued.[3]

Thus has the Mathematical Tripos been divided into two parts; and thus has surely arisen in the University a mathematical examination of a higher type than has been known before, or could have existed under any system in which all the candidates for mathematical honours were required to be examined by the same papers throughout. For those who study mathematics for the sake of exact knowledge or mental discipline, and who propose to go forth into the world to follow professional or other careers, the first part secures all the old stimulus to industry, and gives to those who are successful the same stamp of intellectual distinction as before: such students are released at the end of their third year to enter upon the active duties of their lives, equipped with a sound understanding of the principles of the exact sciences, and with minds well trained to accurate habits in reasoning and in the acquisition of knowledge. To those whose attachment to our science lies deeper, and whose studies have carried them beyond its threshold, the second part, at the end of their fourth year, affords an opportunity of distinction of a higher kind, and one more suited to their tastes: no longer is the wise and thoughtful student hopelessly distanced in the Tripos race by his quick and ready rival.

The wants of the candidate whose mathematical career closes with the last paper in Part I., and of the candidate whose mathematical life only begins from this moment, are equally provided for by the new scheme. The order of merit relates to an examination that can bear it. All the subjects included in Part I. are such as ought to be the common property of every one who has received a sound mathematical education; and by the results of an examination in subjects which all the candidates should have read a list in order of merit can properly be formed. The specialist for the first time is set free to follow his own tastes, and give his whole heart and time to the branches of mathematics by which he is attracted. The University permits him to select any subjects he pleases from the whole range of pure and applied mathematics, and undertakes to examine him in them and award to him the credit he deserves for his attainments. A perfectly free choice is given to him, subject only to the one condition that, in order to qualify himself for admission to the first class, he must not select all his subjects from a single division.[1]

But what to us as mathematicians is more than all, as bearing on the future of our science, is that now for the first time will it be possible in Cambridge for an able and earnest worker and teacher to interest and engage his pupils in his work, and found a school such as we are so familiar with in foreign Universities, where the presence of a great professor has been almost invariably marked by a succession of illustrious pupils—pupils worthy of their master, and worthy to carry on his work. Think of the school of arithmeticians founded by Gauss at Göttingen, and how impossible such a result would have been at Cambridge, dominated as she has been by the competition for places in the Tripos! Great as has been the value to the University of the order of merit—as a stimulus to industry, an encouragement to thoroughness in mathematical study, and a paramount influence in regulating elections to Fellowships at colleges where no independent examination existed—it has yet been in recent years a deadly enemy to the spread of research and the advance of our science. Throughout his whole career the student has had to devote himself unremittingly to the work for his Tripos, taking up a fresh subject each term, and often having to read two in one term. He could never pursue any subject far enough to reach the really interesting portions of it, or obtain complete

[1] Although the Board were unable to make any recommendation upon the subject, I may mention that the principle of prefixing to the final three days a preliminary day, in which the subjects of examination should be those parts of higher pure mathematics which are needed in mathematical physics, found a considerable amount of favour on the Board. The proposal, however, was found to be more difficult in execution than was anticipated (partly on account of the impossibility of forming a perfectly satisfactory schedule of subjects for this day), and was ultimately abandoned by most of its original supporters.

[2] In the first examination in Part III., in 1883, the examiners set, as one of the question papers, a paper of essays; and their example was followed by the examiners in 1884, 1885, and 1886. These essay papers were introduced merely on the authority of the examiners, and not in consequence of any new regulation. Experience seems to show that the essay paper affords very little additional assistance in ascertaining the relative merits of the candidates. The essays were, perhaps, more useful at first, when they were a novelty.

[3] Unless the office should be revived at some future time, there will therefore have been only one Additional Examiner for the final part of the examination, viz. in 1886, the last occasion of the examination taking place in January.

[1] This condition would be complied with by the candidate's showing proficiency in one subject taken from one division and in one other subject taken from one other division. The intention of the Board was to discourage students from specialising too narrowly at too early a period Some of the divisions (as, for example, the fourth, which contains only projective geometry and analytical geometry of curves and surfaces) are so restricted that it was considered undesirable that students should be allowed to confine themselves entirely to subjects chosen from a single division.

command over its methods: he was always occupied with something new, starting afresh and gaining familiarity with new principles, new processes, new modes of thought. Many of the higher lecturers in the University were necessarily neglected by the students: they could pay but scant attention to any subject which was not adequately represented in the Tripos, and even in the case of the subjects which were so represented they were tempted to pass lightly over those investigations, however important, which from their length and character were unsuitable for reproduction in an examination. Now, however, all this is history. When a good course of lectures upon any high subject is given in the University, those students who have attended the course will send in that subject as one on which they desire to be examined: it will, therefore, be properly represented by questions; and the subject will become one that will be increasingly studied year by year. It will now be possible for any capable mathematician, by means of his lectures, to gather pupils round him who will bring his subject into prominence, and make it one of special study in the University.[1] It has been said that in mathematics we have in England generals without armies: the great men who are independent of circumstances have arisen among us, but where are the rank and file? It is my belief that the great obstacle to the existence of the rank and file has now been removed.

Whatever else it may be, Part II. is at all events a "limiting form." No wider choice of subjects could be given to the candidates; no greater freedom to the examiners. The schedule of subjects includes all mathematics: the examiners may issue any kind of list. By introducing numerous divisions into the classes they may make it approximate as closely as they please to an order of merit; or, on the other hand, they may make it merely a class list. They are empowered to give to their list just such a form as they feel justified in doing by the results of the examination. In the appointment of examiners, also, the limiting form has been reached, all four being nominated by the same University authority, and holding office for one year only.

With respect to Part I., it may be that the ultimate form has not yet been reached. There are some who think that, as in some other Triposes, the students should have the option of becoming candidates at the end of their second year. It would seem, also, that the range of subjects is rather too restricted; and, as may be inferred from what I have said near the beginning of my address, I should myself like to see the elementary portions of elliptic functions included in the schedule of Part I. Still, these are but minor points; and I think that the principle of subjecting all the candidates for mathematical honours to one and the same examination in comparatively elementary subjects, and arranging the list in order of merit, meets with general approval.

A few years ago, when the old Tripos was exerting its stifling influence upon the higher mathematical studies of the Universities, I felt disposed to welcome the abolition of the order of merit as the lesser of two evils; but now that the Tripos is divided, and that the mathematician has his own examination especially framed for him, I should be sorry to see a modified class list substituted for the order of merit in Part I. A severe competition for places has the great advantages of keeping the candidates closely employed, and extracting from them their best work. At present an immense amount of thoroughly good mathematical work is done in the University. We have received from our predecessors a system under which the principles of mathematics are efficiently taught, the powers of the students are exerted to the utmost, and upwards of a hundred persons each year receive a mathematical education which is in some respects unique. These are substantial advantages which should not lightly be jeopardised or exchanged for others that are problematical. Under any other system I think the quantity and the quality of the mathematical work done in the University would suffer. It should be remembered also that there is no subject in which the knowledge of a candidate can be so readily tested by examination as in mathematics, and that in no other subject can the results of an examination be expressed with such certainty and accuracy by an order of merit.

I believe there are indeed but very few who have graduated in the Tripos who would set a slight value upon the advantage which their mathematical training has been to them throughout life; and on the other hand I think that it has been an indirect benefit to our science that among those who have won distinction in public and professional life there have always been some—and those not the least influential or eminent—who have passed through an extensive and thorough course of mathematical study, and to whom our world of symbols is no *terra incognita*. The fact that our results, unlike the conquests of astronomy and other branches of applied mathematics, can only be expressed by means of a language of their own, requiring years of study, imposes of necessity such narrow limitations upon the numbers of our audience that we cannot be insensible to the advantages of any system by which the power of understanding and appreciating the beauties of our science is extended to others external to our own ranks. Under the new scheme these advantages are still retained; and, difficult as is the problem of combining a mathematical course for the many with the technical requirements of the few, I believe that a satisfactory solution has rewarded the efforts of the last twenty years. I believe that the University of Cambridge will become a great centre of mathematical research and a home of the exact sciences, and that it will be found that these objects have been attained without any sacrifice of the general efficiency of the training received by the bulk of the candidates for mathematical honours.

On taking a survey of the history of the Tripos during the last half century, perhaps the feature that stands out most strongly is the part played by the subjects of electricity and magnetism—their half-recognised existence before 1848, their exclusion until 1873, and the effects which followed their restoration in that year. It was the extension of the dominion of mathematics over these great and growing branches of physical science that broke down the old system. Electricity and magnetism became too important to be excluded; but when included the examination in its old form was too heavily weighted to exist.

The year 1877-78, in which the syndicate of 1877 was endeavouring to frame a scheme that should relieve the strain of the excessive competition without sacrificing the order of merit, was perhaps the most eventful period in the whole history of the examination: it then became evident that it was impossible to retain the existing system even in a modified form, and that a complete reorganisation of some kind was inevitable. Although the frequent changes in the last few years have been productive of some inconvenience, I think it is fortunate that the syndicate was so reluctant to propose any sweeping changes, and that the present scheme has come into existence as it has done—not as the work of any influential legislator, but as the form which the examination has of itself assumed under the pressure of the actual forces at work in the University. The order of merit for the whole examination was not given up till it was clearly shown that its retention was an impossibility; and, on the other hand, Part II. has grown up by a process of regular development, and been moulded into

[1] In the schedule for Part II. no subjects are ignored or favoured less than others, so that by the new scheme provision is made for the growth of any subject which may happen to take root.

its present form by those most interested in promoting the higher mathematical studies of the University.

Special reference also should be made to the "three days." It will be remembered that this preliminary portion of the examination was the principal feature of the scheme which came into operation in 1848. Both the subjects and the methods of solution that may be employed are defined by a schedule, and only those who satisfy the examiners by their performances in these three days are admitted to the subsequent parts of the examination. It is very singular that an arrangement devised so long ago should not only still continue in force, but even be regarded by some as the most thoroughly satisfactory portion of the whole system. The framers of this scheme and schedule might well have been proud of the lasting character of their work if they could have known that it would outlive two sets of University statutes, and, amidst changes on every side, remain unchanged for forty years.

The early history of the Tripos and its gradual development into an examination by written answers, and finally by printed papers also, are especially interesting in these days, when the merits of the examination system are so highly appreciated, and its adoption is so universal. The Senate House at Cambridge is the cradle of the modern form of examination in England.

In connection with the Tripos there is one matter of so much importance that I cannot pass over it entirely without mention. I mean the influence of the system of private tuition. I believe that while there is an order of merit it will always be a great assistance to the majority of the candidates to read with a private tutor. Mathematics is a difficult science; and when a considerable range of subjects has to be traversed in a comparatively short time, and the knowledge of the candidate has to be finally tested by an examination such as Part I. of the Tripos, it cannot fail to be a great advantage to him to have his difficulties explained, his path smoothed, and his skill in working out problems developed, by an experienced private tutor specially interested in his individual welfare. The system of private tuition has been objected to from two points of view: (1) because it is unsatisfactory that the instruction which is valued most highly by the student should be received from his private tutor instead of from college lecturers or University professors; and (2) because the student who has followed implicitly, during his whole undergraduate career, the minute directions of one man with regard to his reading, is placed after his degree, when he is deprived of his guide, in a very unfavourable position for pursuing further his mathematical studies. The first objection does not concern us here: my own feeling is, as I have just said, that, whenever an order of merit exists and the competition for places is keen, the services of private tutors will necessarily be called into requisition. The second objection is one which is of far more importance to our science. There can be no question that, brilliant and eminent as have been the greatest of the private tutors at Cambridge, one result of the system has been that many of the ablest students have been left after graduation not only without any knowledge of the way to follow up the study of the subjects of which they had learned the elements, but even without any taste or inclination to do so. The private tutor's manuscript and verbal instruction had superseded all need of referring to the original memoirs, and the nascent wrangler knew nothing of the great world of mathematical literature or of the modes of reaching it. On the other hand, it is only fair to say that the amount of mathematical knowledge acquired by the best pupils from their private tutors in the course of their undergraduate career was really wonderful; and that till quite recently neither the University nor the colleges offered any inducement to the mathematical student to continue his reading after the Tripos. The fact that the student's horizon should have been bounded by the Tripos, and that his training should have been directed with the view to giving him skill in working out questions rather than to developing his taste for the science he was studying, was principally the fault of the system as a whole; but it was certainly intensified by the complete subjection of the pupil to the course of reading placed before him by the private tutor. A student whose interests and aspirations had been at least held in check, and perhaps entirely stifled, throughout his whole undergraduate career, was generally too subdued or helpless to be able to make use of his freedom when the examination was over.

Under the new scheme the private tutor still occupies in the main his old position with respect to Part I., although, of course, the higher places in this examination have much less significance than before. With respect to Part II. it is quite different. No attempt is made by private tutors to teach these higher subjects, which, both from their character and extent, are clearly unsuited for private tuition; and the students are compelled to rely upon the lectures delivered in the colleges and University in their preparation for this final examination. Thus, in their fourth year they are brought into contact with the leading mathematicians in Cambridge; and when the examination sets them free to pursue their own studies or researches, they start on their new career fresh from the best teaching which the University affords.

Although the subject of my address is the Mathematical Tripos, it may be regarded as still falling within my province to refer to other changes that have taken place in the University for the purpose of encouraging original mathematical work. Fourteen years ago Trinity College invited mathematical candidates for Fellowships to send in, before the examination, dissertations upon any subjects of their own selection. It was announced that these dissertations, if possessed of decided merit, would be taken into account in the Fellowship election, together with the results of the Fellowship examination. Not only have these dissertations been of the greatest value in guiding the choice of the electors, but many of them have been important contributions to mathematical literature.[1] The example of Trinity College has been recently followed by St. John's College and King's College. The Smith's Prizes, which for a great number of years had been awarded by a special examination, are now awarded annually for mathematical dissertations, the candidates being free to select their own subjects. This new scheme passed the Senate on October 25, 1883, and the first award of the prizes under it was made in 1885. Powerful inducements are, therefore, now held out by the University and some of the colleges for the best students to devote themselves to original work. The importance to our science of these direct incentives to research cannot be overestimated. They come into operation as soon as the stimulus of the examination is removed, and, instead of resting upon their laurels, the ablest mathematicians of the year are induced to concentrate their powers upon a single subject, just at the time when they are undaunted by any amount of hard work, when their stock of general mathematical knowledge is freshly acquired, and when their minds are flexible, vigorous, and free from care. It is indeed strange to look back upon the changes of the last few years, and to contrast the encouragement now

[1] Among the Trinity dissertations which have subsequently been printed, I may mention the late Mr. R. C. Rowe's "Memoir on Abel's Theorem" (*Phil. Trans.*, 1881), Mr. Forsyth's "Memoir on the Theta Functions" (*Phil. Trans.*, 1882), Mr. Homersham Cox's "Application of Quaternions and Grassmann's Ausdehnungslehre to different kinds of Uniform Space" (*Camb Trans.*, 1882), Mr. Gallop's "Distribution of Electricity on the Circular Disc and Spherical Bowl" (*Quart. Math Journ.*, 1886), and Mr. R. Lachlan's "Systems of Circles and Spheres" (*Phil. Trans.*, 1886).

given to mathematical research with the indifference, or even worse, of twenty years ago.[1]

I cannot close my address without saying a few words upon our Society. We were founded in 1865, and so to-day we attain our majority. I think we can safely say that we have steadily and uniformly kept to our single purpose of promoting the advance of mathematics. We have published seventeen volumes of *Proceedings*, and every paper we have printed has been subjected to a rigorous examination by two referees. We already have a history to look back upon: familiar presences among us—De Morgan, Clerk Maxwell, Clifford, Henry J. S. Smith, Spottiswoode—have passed away; and for most of us this very room is full of associations with those whom we shall see no more. I should like before concluding to formally express our gratitude to our two Secretaries, Mr. Morgan Jenkins and Mr. Robert Tucker, who have served us so faithfully almost from our foundation, and to whom the successful development of our Society has been largely due. I will not utter any aspirations with regard to our future: we shall never be a great Society in numbers, but we can continue to do what we have done, and to spare no effort to encourage the advance of mathematical science.

THE INTERNATIONAL COMMITTEE OF WEIGHTS AND MEASURES

THE results of the scientific investigations made under the directions of the Comité International des Poids et Mesures at their Bureau at Sèvres during the past year are stated in vol. v. of their "Travaux et Mémoires," recently published (Gauthier-Villars, Paris, 1886) under the authority of the Director of the Bureau. This volume contains the following papers:—"Note sur l'étallonage des sous-divisions d'une règle, sur l'étude des erreurs progressives d'une vis micrométrique, et sur le calibrage des thermomètres," by Dr. O. J. Broch; "Études thermométriques," by M. Ch. Ed. Guillaume; "Études sur la balance," by Dr. M. Thiesen; "Sur quelques analyses chimiques faites pour le Bureau International," by M. Tornöe. The two latter memoirs, however, are published under the responsibility of their authors.

In the method of calculating the errors of the subdivisions of a standard measure of length, or of calibrating a thermometer, Dr. Broch has followed the celebrated astronomer P. A. Hansen; but he has endeavoured to render Hansen's method more simple; and he has abbreviated it and reduced the number of observations, without increasing the probable error of the results obtained. Convenient tables of equations are given for the more ready application of Hansen's formula, and also examples of an abbreviated method for calculating the several lengths of the decimetres, centimetres, and millimetres on a subdivided standard metre.

The second part of this Note deals with the progressive errors of the micrometer-screw. As each interval to be measured on a linear standard is contained within two lines, we have to pass by successive turns of the micrometer-screw from one line to the other. Each line in turn is bisected by means of cross or of parallel webs; and not only do the personal errors of bisection have, of course, to be allowed for, but even small errors in the micrometer-screw itself have to be corrected. Examples of such corrections are given in this note. In considering the progressive errors of micrometer-screws, we are not sure that Dr. Broch has sufficiently, however, investigated the variation in the amounts of such errors owing to the wear of the screw.

In the third part of the note is given an explanation of an abbreviated method of calibrating graduated glass tubes or thermometer-stems, and of applying corrections to the calibrated lines. The method of interpolation by differences is also discussed and simplified.

Dr. Guillaume, in his "Études thermométriques," continues the thermometric work which was begun by Dr. Benoit, and by Pernet at this Bureau. It is required of all standard thermometers verified at the Bureau, that they should carry the fundamental points 0° and 100° C.; that they should have a total length of as much as 70 centimetres, the diameter of the stem varying from 3·5 to 5·5 millimetres; and that each division should be nearly 5 millimetres in length. The testing of the thermometers includes the three distinct operations:—

(1) Division and calibration.

(2) Determination of the coefficient of pressure (when the thermometer is placed alternately in a vertical and in a horizontal position).

(3) Determination of the fundamental points and of the mean value of each degree.

It is with these operations, as well as with the actual verification of certain standard thermometers at the Bureau since the year 1883, that Dr. Guillaume now deals. The paper is an interesting one, and all the observations are printed in the fullest detail. Particularly in that part of this paper which discusses the variations in the readings of thermometers by time and circumstance, there is much to be learnt.

Of late, attention has been given, especially in Germany, to the kind of glass best adapted for thermometers, the zero-points of thermometers made of some kinds of glass, being found less likely to alter by age like ordinary thermometers. A careful analysis made by M. Tornöe of the glass used for the bulbs of two of Tonnelot's thermometers used at the Bureau, gave the following results:—

	Hard glass	Plate glass
Silica	71·52	60·68
Sulphuric acid	0·72	0·37
Chlorine	traces	—
Peroxide of iron	0·22	—
Lime	14·55	5·44
Soda	10·81	10·50
Potash	0·37	6·55
Magnesia	traces	traces
Protoxide of manganese	traces	—
Oxide of lead	—	15·12
Alumina	—	—
Alumina, with traces of iron and manganese	—	0·87

The analyses of the stems of the thermometers showed somewhat different results.

The memoir by Dr. Thiesen, "Études sur la balance," continues the excellent work on the construction and use of the balance which was originally begun at the Bureau by M. Marek. In the "Théorie générale de l'équilibre statique de la balance," and in the "Calcul de l'équilibre de la balance," Dr. Thiesen has discussed the conditions which affect the equilibrity of a balance, and also has investigated the effects of outside influences during weighings, as those arising from currents of air and from changes in the condition of the air; and from electrical disturbances, magnetic and radiometric. A good balance may be relied on to 0·001 mgr. in the comparison of two standard kilogramme weights, but outside influences increase the probable error to ± 0·004 mgr.

The labours of the Bureau have been particularly devoted to the perfecting of existing methods, and they have resulted in the attainment of far higher accuracy in weighing and measuring than was thought to be possible, or necessary, even ten years ago. We trust that the labours of the Comité may soon be crowned by the completion of the international metric standards of length and weight, for which all their present investigations are preparatory.

[1] Under the old system, the Cambridge graduate who devoted himself to mathematical research possessed one advantage over his Continental colleagues in the wider range of his general mathematical knowledge. Although Part I. is considerably more restricted than the Tripos of 1848-72, this advantage is still retained to a substantial extent.

NOTES

MR. C. L. GRIESBACH, lately geologist to the Afghan Boundary Commission, and deputy superintendent of the Geological Survey of India, has been appointed by the Viceroy to officiate as superintendent.

THE annual meeting of the Association for the Improvement of Geometrical Teaching will be held on Friday, January 14, 1887 (11.30 a.m.) at University College, Gower Street. At the afternoon meeting (2 p.m.) the following papers will be read:—"On the Teaching of Modern Geometry," Rev. G. Richardson; "The Modern Treatment of Maxima and Minima," Rev. J. J. Milne; and on "Geometry from an Artist's Point of View," G. A. Storey, A.R.A. The meetings are open to all who are interested in the objects of the Association.

OUR readers will be interested to hear that at the meeting of the British Association recently held in Birmingham, a movement was originated in the Committee of Section D (Biology) having for its object an application to Government for a small grant out of the Civil List to Mr. Thomas Bolton of Birmingham, whose important services to science as a naturalist and microscopist have long been well known and appreciated. A memorial setting forth Mr. Bolton's claims was prepared by Mr. W. R. Hughes, late President of the Birmingham Natural History and Microscopical Society, and was signed by Sir J. W. Dawson, the President of the British Association, and by a large number of eminent men of science. It also received the signature of the Mayor of Birmingham. The memorial was recently presented to Lord Salisbury as First Lord of the Treasury, who has recommended that Her Majesty grant Mr. Bolton a Civil List pension of 50*l.* per annum.

THE finest of all Japanese botanical books is the Honzo Dsufu. It is also from a scientific point of view the most valuable, inasmuch as it contains excellent coloured figures of no less than 1500 species of Japanese plants, of many of which there are no other published representations. Franchet and Savatier, in their "Enumeratio plantarum in Japonia sponte nascentium," quote throughout the copy in their possession, which was not, however, quite complete. It is in ninety-six volumes, or rather *livraisons*, and is rare even in Japan. It was prefaced in 1828, but only the first six *livraisons* have ever been printed, and the rest only exists in hand-made copies. It has long been desired to obtain a copy for the library of the Royal Gardens, Kew, and this wish has at length been gratified by the kind liberality of Mr. Tokutaro Ito, grandson of the well-known Japanese botanist, Keisuke Ito. Mr. Ito is now studying botany at the University of Cambridge, and lately communicated a revision of Japanese *Berberidaceæ* to the Linnean Society, of which he has recently been elected a Fellow. The Kew copy of the Honzo Dsufu is probably the finest to be obtained in Japan. It came from the library of Senator Tanaka (himself a distinguished botanist), who, with extraordinary generosity, placed it at the disposal of Mr. Ito for presentation to Kew.

IN the *Annalen* of the Vienna Natural History Museum, Herr von Pelzeln and Dr. von Lorenz have just published the first of a series of articles on the types of birds contained in that Museum. This cannot fail to be of the greatest use to students, who often require to know the present resting-place of typical specimens. Following the Cuvierian arrangement as adapted by Gray in his "Hand-list of Birds," the authors present, as a first instalment, a list of the types of the *Accipitres* and *Tenuirostres*. The chief interest naturally centres round the species procured by Johann Natterer in Brazil, for nothing more wonderful is known in the history of ornithology than the way in which Natterer's collections, made in the early part of the present century, still remain the basis of our knowledge of the ornithology of that country, and, notwithstanding the subsequent efforts of travellers, there are numbers of Brazilian species obtained by Natterer alone, and unrepresented in any Museum except that of Vienna. Curiously enough, too, the Vienna Museum also possesses several of Latham's and Shaw's types, founded on the specimens in the Leverian collection, and purchased in 1806. The value of a type was not understood in England so long ago as 1806, and the specimens were allowed to leave the country, to find a home in Austria. Such would scarcely be permitted now, under the enlightened management of our authorities at the Natural History Museum at South Kensington, who are doubtless mindful of the disgrace attaching to the British Museum in former years, when that institution allowed the whole of the Gould collection of Australian birds, with its 300 types, to go for 1000*l.* to America, where it now lies, scarcely heeded, in the Museum of the Academy of Natural Sciences of Philadelphia. Let us hope that the Gouldian types are better looked after in the Philadelphia Museum than some of the types of Du Chaillu's Gaboon species, which are no longer forthcoming, to the no small embarrassment of ornithological students.

PROF. MENZBIER has recently published, in the *Bulletin* of the Society of Naturalists of Moscow, an account of the birds collected by Mr. Zaroudnoi, a Russian naturalist, who has been exploring the oasis of Akhal-Tekké, the Kara-Kum desert, and the adjacent mountains, in Central Asia. The want of funds appears to have crippled the efforts of the traveller to a great extent, but he managed to procure 184 different species of birds, though his observations were confined to the summer months and early autumn. Mr. Zaroudnoï found several rare species nesting, and besides his own observations there are some interesting scientific notes from Prof. Menzbier's pen. We are informed that the traveller has recently prosecuted a further expedition into Khorasan and Northern Afghanistan, the results of which may be expected to be of considerable importance to zoologists.

THE *Auk*, which is the journal of the American Ornithologists' Union, and answers to our English *Ibis*, has just completed its third volume, under the able editorship of Mr. J. A. Allen, who is the President of the American Ornithologists' Union. The present volume abounds in interesting memoirs, and fully maintains the high standard of the journal. The Union now numbers 46 active members, 112 associate members, 26 foreign members, and 59 corresponding members. The Committees on the Migration and Geographical Distribution of North American Birds and for the Protection of North American Birds have both done excellent service during the past twelvemonth.

MR. G. H. HINSBY, of Hobart Town, has forwarded us a useful list of the birds of Tasmania: 178 species are found in the island, but the author is apparently unaware that several Tasmanian birds to which he gives the same scientific name as the Australian species are considered by recent writers to be peculiar to Tasmania itself.

A RECENT issue of the *Japan Weekly Mail* contains a report of the Japan Educational Society, an association founded to bring together persons interested in education, to assist in its diffusion, and to improve and advance education in the country. Besides general and ordinary meetings in furtherance of the objects of the Society, members are frequently sent to various localities at the request of local educational institutes for the purpose of delivering addresses or lectures. Thirty-three numbers of the memoirs have been published, the total number printed being 100,000. In addition, books under the title "Hints to Educators" were published, and 7000 copies printed. The number of members is 3000, and a prince of the Imperial House is President.

UNDER the title of a "Descriptive List of Native Plants of South Australia recommended for Cultivation," Mr. J. G. Otto Tepper, F.L.S., has reprinted in pamphlet form some notes that apparently appeared periodically in Adelaide. As a reason for publishing the list Mr. Tepper says:—"At the rate South Australia and its sister colonies are progressing in civilisation, the time can easily be foreseen when for long distances from any centre of population not a mark would be discoverable where any one could view the native vegetation in its natural state. Owing to the very local distribution of many Australian herbs, shrubs, and trees, there is even the possibility that they may be entirely extirpated, caused by ruthless and ill-judged clearing, depasturing of domestic animals, choking by introduced weeds, and the diminution of the moisture in the soil by the first two causes. Few attempts are made to cultivate any, so far as we know, though a few (for example *Kennedya monophylla*) have already found their way to the favour of gardeners, who, perhaps, do not even know that these plants are indigenous." The list consists of a number of plants belonging to very different natural orders and of very different characters, such as herbs, trees, shrubs, &c., as may be instanced by species of *Mesembryanthemum*, *Viola*, *Acacia melanoxylon*, &c., &c. To each plant its habit and size are given, a short description of the leaves and flowers, time of flowering, and nature of locality where found. The descriptions, however, are by no means equal in point of detail, some being considerably longer than others. To some of the plants the natural orders are stated, while to others no mention whatever is made. No references are made to the uses of the plants, and no kind of arrangement of genera has been adopted, either scientifically, alphabetically, or in any other way. The list may be of use to those for whom it has been written, but it would have been more valuable if some arrangement had been adopted by which any given plant could have been found without wading through the whole nineteen pages.

MR. STEVENS, the Queensland naturalist whose visit to the Veddas of Ceylon we have already mentioned, addressed a recent meeting of the Asiatic Society of Ceylon on this little-known people. He found the time at his disposal on his first visit too short to investigate satisfactorily the problem of their origin, but he intends going amongst them for another six months on his approaching return from India. He has offered to live with them for a year or two if such a long absence from his other duties can be arranged. He regards the popular notion in Ceylon of the Veddas as a cruel, vindictive, suspicious people as wholly erroneous. He found them truthful, hospitable, and honest, but they exhibit a marked aversion to Singhalese and Tamils. They are very peaceful, and hence a European can travel amongst them in perfect safety and freedom. They have a language of their own which the Singhalese do not understand, and of which he collected a considerable number of words for examination by Oriental scholars. They are expert archers, and can send an arrow completely through a wild animal. Mr. Stevens would prefer to face a rifle in the hands of an experienced person at fifty yards' distance rather than a Vedda armed with his bow. They have no idea of boiling anything; they use the fire-drill, and they appear to have had sufficient knowledge of working in metals to supply themselves with weapons. He questions whether there are 500 Veddas in all Ceylon, so that soon it will be difficult to find a real one. Hence he urges the great importance to science of a thorough study now of their language and habits. Demonology is, he thinks, an incorrect term to apply to their religion; it is, rather, "Kapuism." They do not believe in the existence of any injurious or malevolent spirits. Once a year the whole of a Vedda encampment make a propitiation; it is not worship, but simply a propitiation to the eight or nine gods of their pantheon. They divide themselves into eight clans, which rank in a kind of social gradation, depending, in some instances, apparently on their traditional origin. He obtained skulls of representatives of seven of these clans. Throughout the address, Mr. Stevens constantly insisted on the tentative nature of his investigations so far. His facts, "or, rather, supposed facts," are entirely unverified. They require assortment and further examination, and he urges societies and students in Ceylon to undertake the work. It is greatly to be hoped that Mr. Stevens himself may be able to carry out his project of residing amongst the Veddas for a prolonged period, and studying them from the inside, and, in a certain degree, as one of themselves. One of his facts requires no verification, viz. that he can live and travel amongst them with safety, and that he has the capacity for making friends of them.

M. DE QUATREFAGES, at a recent meeting of the Geographical Society of Paris, advanced the theory with regard to the migration of peoples at a remote period of antiquity, which, at a subsequent meeting, was discussed and approved by M. H. Chevalier. The theory is that these migrations were due essentially to the gradual increase of cold in the northern regions, which forced the inhabitants to wander to the south in search of a more temperate climate. M. Chevalier quoted certain passages from the Zend Avesta, which, he argued, corroborated this theory.

A PROSPECTUS has been issued by the Council of the "Lochbuie Marine Institute" on the Isle of Mull, recently established under the auspices of the National Fish Culture Association, setting forth their objects. One of these is to incubate herring-ova to re-stock such locations in Scotland as have been depleted of that fish through the action of fishermen in exhausting the supply under the belief that they were general instead of local. Meteorological and other observations are also to be carried out under the direction of Mr. Anderson Smith.

DR. FOREL sends us the following list of recent earthquakes in Switzerland:—December 16, 16h. 0m., at Sarnen (Unterwalden); 22, 0h. 3m., 4h. 20m., and 5h. 30m., at Pontresina (Grisons), all Greenwich time.

WE have referred on several occasions to the extraordinary number of rats which emerge from various parts of the building when the late Exhibitions at South Kensington have closed and the supply of food is cut off. This year their number has been larger than ever, and shortly after the termination of the late Colonial and Indian Exhibition the rats, desperate with hunger, invaded every part. During the summer nothing would induce them to enter traps, whereas now they rush in as fast as they are set, and not until they have devoured the bait do they seem to realise the fact that they are prisoners, when they seek deliverance in their usual wild fashion. During last week their cravings for food culminated in a fierce onslaught upon one another, which was evidenced by the piteous cries of those being devoured. Their method of seizing their victim is to suddenly make a raid upon one weaker or smaller than themselves, and after overpowering it by numbers, they tear it in pieces. At the present time there cannot be found a single young rat in the building. So far this is satisfactory, as the large numbers bred during the summer will thus become exterminated.

AT present the city of Worcester possesses a public free library and natural history museum in one building, and a Government school of art in another. It is proposed to celebrate the Queen's Jubilee by establishing an institution to be called the Victoria Institute in a central position in the city, in which the existing library, museum, and school of art will be placed, and to unite with them in the same building a school of science and an art gallery. The cost is estimated at 18,000*l*., of which the Corporation have voted 7000*l*., and the old site and other sources of income will leave only about 5000*l*. to be raised by public subscription. A considerable portion of this amount has already been raised.

A LATE issue of the Batavia *Dagblad* contains a report of a paper read by Dr. Cornelissen, of the Java Medical Service, before the Society for the Advancement of Medical Science of Java, on his researches in Acheen, in Sumatra, into the causes of the dreaded disease *beri-beri*, known as *kakke* in Japan—a species of elephantiasis. Dr. Cornelissen comes to the unexpected conclusion that it is infectious, and is propagated by bacilli. He accordingly recommends a thorough system of disinfection in hospitals and troop-ships where patients suffering from this malady have been kept. The theory has caused much excitement in Java and the neighbouring regions where the disease prevails, for it has not hitherto been suspected that it was infectious. Dr. Cornelissen's theory, however, does not appear to be generally accepted in Java and the Straits Settlements.

IN the current number (27) of *Excursions et Reconnaissances* of Saigon, M. Aymonier brings to a conclusion his notes on Annam, the particular province dealt with being Khanh-Hoa. The most interesting part of the paper is the sketch of the so-called savages, or Mois, inhabiting the mountains of the province. These papers have now been running through many numbers of the periodical, and are encyclopædic in their nature. M. Aymonier is, beyond question, the greatest living authority on Cochin China generally, and he undertook prolonged journeys into various parts of the country with a view to perfecting his information for this series. His original intention was to explore the whole coast of Annam up to Tonquin, but the rebellion of 1885, which resulted in frightful massacres of missionaries and native Christians, prevented him from carrying out this project. Accordingly in his "Notes" he has been compelled to omit all reference to the ancient kingdom of Ciampa, as well as to a great part of Annam, and to confine himself to the two great southern provinces Binh Thuan and Khanh-Hoa, which stretch from Ciampa on the coast across to Cambodia. Capt. Réveillère, who has already twice navigated the Meikong rapids in a gunboat, describes a voyage on that river in a steam-launch. The Meikong can scarcely be said to be a new river to geography, inasmuch as the greater part of its course was described with great minuteness in the work recounting the details of La Grée and Garnier's expedition from Saigon along the Meikong to the Yangtsze, published ten or twelve years ago. Father Azemar describes the Stiengs, amongst whom he lived between 1861 and 1866, and gives a vocabulary of their language. The Stiengs form one of those wild tribes which inhabit the mountains between Cochin China and Tonquin on the east and Laos and Siam on the west. The writer thinks they have no ethnic affinity with the Mongol family, mainly basing his opinion on differences in language and manners.

PERHAPS the most important point to be noticed about the Perthshire Society of Natural Science, the *Proceedings* of which for the past year we have received, is that the present method of publication has been abandoned. For six years past the *Proceedings* have, for the most part, been reprinted from the reports of the meetings which have appeared in a local newspaper. But the selection and arrangement of matter most suited to a newspaper were not always the best adapted for the *Proceedings* of a scientific Society. The Council have, therefore decided to commence a new series of *Transactions* and *Proceedings*, which will be specially printed for the Society, under the supervision of a publishing Committee. An examination of the *Proceedings* now before us certainly reveals so much activity in many departments of research that the Council appear justified in this resolution. It is especially noticeable that the papers read refer, almost without exception, to local investigation—in our judgment the most valuable and instructive work in which the members of such a Society could systematically engage. Thus, we have some notes on a collection of nests and eggs presented by a local landowner; a thorough description, by several hands, of the natural history of Kinnoull Hill, under the heads of Introductory, Geology, Flowering Plants, Ferns, Mosses and Fungi, Insects, Mollusca, and Vertebrates, and many others of the same kind. Dr. Buchanan White's address this year, as last, urges the improvement of the museum, with a view to securing more space for the exhibition of the collections. He dwells on the value of a properly selected and arranged museum as an educational medium for the members of the Society, and, quoting the words we used last year in regard to this subject, that a local museum, to be of the fullest value, should be made as complete as possible, he explains what degree of completion he expects such a museum to attain.

WE have received the *Proceedings* of the Holmesdale Natural History Club, with its home at Reigate, for 1884 and 1885. The papers are of a very general kind, ranging from the continuity of protoplasm to the wild animals of South Africa, and from mahogany to the Yellowstone National Park. Students will probably turn with most interest to two papers by Mr. W. H. Beeby on recent additions to the flora of Surrey, Mr. Tyndall's meteorological notes for the two years, and Mr. Crosfield's paper on the geographical distribution of wild plants in the British Isles.

THE Town Council of Bombay has unanimously resolved that the municipality must bear its share, with the Government and other public bodies, in the expenses of the establishment of a technical school, and a sum of 5000 rupees was voted for the purpose at a late meeting. The scheme is one drawn up by Dr. Cooke, Principal of the Poona College of Science, and explained by him to the Council. The skilled artisans, he said, turned out by the school would be a benefit to the country and to the municipality alike.

THE additions to the Zoological Society's Gardens during the past week include an Indian Rhinoceros (*Rhinoceros unicornis* ♂) from India, presented by the Maharajah of Cooch Behar; a Tiger (*Felis tigris* ♂) from India, presented by the Zoological Gardens, Calcutta; a Chanting Hawk (*Melierax musicus*) from South Africa, a Red-throated Diver (*Colymbus septentrionalis*), European, presented by Lord Lilford, F.Z.S.; a Short-eared Owl (*Asio brachyotus*), British, presented by the Rev. Hubert D. Astley, F.Z.S.; ten Moorish Geckos (*Tarentola mauritanica*) from the borders of the Mediterranean, presented by Mr. J. C. Warburg; three Zebus (*Bos indicus* ♂ ♂ ♂) from India, a Montagu's Harrier (*Circus cineraceus*), European, deposited.

OUR ASTRONOMICAL COLUMN

THE SPECTROSCOPIC METHOD OF DETERMINING THE DISTANCE OF A DOUBLE STAR.—Mr. A. A. Rambaut, in a paper communicated to the Royal Irish Academy on May 24, discusses at some length the possibility of determining the distance of a double star by measures of the relative velocities of the components in the line of sight by means of the spectroscope. Of course, as soon as Dr. Huggins had demonstrated that it was practicable to measure the rate of approach or recession of a star, it was seen that it would be at least theoretically possible to determine the distance of a star by this method, but Mr. Rambaut does not merely repeat the suggestion, but examines the conditions of the problem that he may ascertain what chance there is of putting it into successful operation. His first step is to find the value of ΠV for the satellite star of any binary system, Π being the parallax in seconds of arc, and V the velocity of motion in the line of sight expressed in miles per second. The resulting formula is—

$$\Pi V = \frac{la^2 \sqrt{1 - \epsilon^2} . \sin (\phi - \lambda) \sin \gamma}{Pr \sqrt{1 - \epsilon^2 \cos^2 \phi}} = k,$$

where ϕ denotes the angle between the tangent and major axis,
λ denotes the angle between the line of nodes and major axis,
γ denotes the angle between the plane of orbit and tangent plane to sphere,
P denotes period in years,
l denotes mean motion of earth in miles.

This equation therefore gives a relation between Π and V depending only on the period and the angular elements of the orbit, so that if either Π or V can be measured the other may at once be determined. If k be greater than unity, then either V must exceed ten miles per second, or Π one-tenth of a second of arc. If, then, the spectroscope show the lines in the spectra of both stars to be absolutely coincident, it follows that the parallax must exceed 0″·1, and the star will repay investigation. But if a measurable displacement be noticed, V can be determined, and the parallax will follow at once. So that "all double stars for which k is at any time greater than unity may be said to be within measurable distance either by the spectroscopic or the trigonometrical method." If, however, k be less than unity, the star may still chance to be within a mea urable distance, for V may be small either from the small linear dimensions of the orbit or the length of the period; but if k be smaller than unity, and V be large, then we shall at once know, "with a certainty which the mere failure to measure its parallax trigonometrically could never reach, that the star is at an inconceivable distance from the solar system." Mr. Rambaut next proceeds to determine k for some 39 stars, the elements of whose orbits he takes for the most part from Houzeau's "Vade Mecum." In the case of five only does it exceed unity, viz., α Centauri 6·023, Sirius 5·400, 70 p Ophiuchi 1·270, η Cassiopeiæ 1·247, and γ Coronæ Australis 1·224. Of these the parallax has already been determined for all but the last named. This star, the components of the pair being of nearly equal magnitude, would be well adapted for examination by the spectroscopic method if one of the new giant telescopes were employed, and since $k = 1·224$, had it been examined in 1880 either the velocity in the line of sight would have been found to exceed 12 miles per second, or the parallax to exceed 0″·1. Since a star fainter than the fifth and a half magnitude would be beyond the reach of even the most powerful instrument to successfully measure its movement in the line of sight, the field of inquiry is practically confined to α Centauri, and the following three stars for all of which k is fairly large though less than unity: ξ Ursæ Majoris 0·895, γ Virginis 0·624, and ζ Herculis 0·605. The result of Mr. Rambaut's inquiry is therefore to show that but little practical use can be made of the suggested combination of the two methods in the case of double stars.

NAMES OF MINOR PLANETS.—The following minor planets have recently received names:—No. 254, Augusta; No. 255, Oppavia; No. 257, Silesia; No. 260, Huberta; and No. 261, Prymno.

COMET FINLAY (1886 *e*).—Dr. J. Holetschek gives (*Ast. Nach.*, No. 2763) the following elements and ephemeris for this object, which, though now diminishing somewhat in brightness, becoming well placed for observation in northern latitudes:—

T = 1886 November 22·48418.

$$\left.\begin{array}{l} \omega = 315^\circ\ 21'\ 0''\!\cdot 5 \\ \Omega = 52\ 45\ 43\cdot 2 \\ i = 3\ 1\ 9\cdot 4 \end{array}\right\} \text{Mean Eq. 1886·0.}$$

$\log q = 9·997122$ $\log a = 0·533468$
$\log e = 9·850744$ Period = 6·31 years.

Ephemeris for Berlin Midnight

1887	R.A. h. m. s.	Decl. ° ′	log *r*	log Δ	Brightness
Jan. 0	23 49 17	1 2·3 S.	0·0565	9·9245	2·3
4	0 8 58	1 23·7 N.	0·0670	9·9343	2·1
8	0 28 10	3 45·0	0·0779	9·9461	1·9
12	0 46 52	5 59·9 N.	0·0889	9·9598	1·7

The brightness at the time of discovery is taken as unity.

COMET BARNARD (1886 *f*).—The following ephemeris for Berlin midnight is in continuation of that given in NATURE for December 9 (p. 134):—

1887	R.A. h. m. s.	Decl. ° ′	log *r*	log Δ	Brightness
Jan. 0	19 32 32	4 5·2 N.	9·8652	0·1478	10·5
5	19 53 52	1 13·5 N.	9·8935	0·1845	7·8
10	20 11 46	1 20·1 S.	9·9243	0·2177	5·8

The brightness at the time of discovery is taken as unity.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1887 JANUARY 2-8

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on January 2

Sun rises, 8h. 8m.; souths, 12h. 4m. 14·9s.; sets, 16h. 1m.; decl. on meridian, 22° 55′ S.: Sidereal Time at Sunset, 22h. 49m.

NOTES FROM THE OTAGO UNIVERSITY MUSEUM

IX.—On the Nomenclature of the Brain and its Cavities

In working at the brain of the lower Vertebrata, the inconvenience of the received terminology of the cerebral cavities became so manifest, that I adopted the plan[1] of distinguishing each cavity by the simple expedient of placing before the syllable *cœle* (κοῖλος, κοιλία) the prefix used for the corresponding division of the brain in the systematic nomenclature adopted in Quain's "Anatomy." Thus, the entire cavity of the mid-brain of fishes, for which the usual names "aqueduct of Sylvius" or "iter a tertio ad quartum ventriculum" were unsuitable, became the *mesocœle* or cavity of the mesencephalon, the "lateral ventricles," the *prosocœles* or cavities of the prosencephala, and so on. A similar but more thorough-going reform had been previously and independently proposed by Burt Wilder (*Science*, ii., 1881, pp. 122 and 133), and adopted in Wilder and Gage's "Anatomical Technology" (New York, 1882). Prof. Wilder was good enough to write to me on the subject, and, after some correspondence had passed between us, he published an article[2] giving a full account of the nomenclature he proposed to adopt, and stating that certain of his terms (*e.g. neurocœle* for the entire cavity of the cerebro-spinal axis, and *encephalocœle* for the entire system of brain-cavities) had been proposed by me.

The chief features in Wilder's nomenclature are the following:—

(*a*) The adoption of *diencephalon* in preference to the more cumbrous *thalamencephalon* as the systematic name of the 'tween-brain (*Zwischenhirn*). The former term is given as a synonym by Allen Thomson (Quain's "Anatomy," ninth edition, vol. ii. p. 828), and is used by Rolleston in "Forms of Animal Life." In correspondence with this, the third ventricle becomes the *diacœle* (*thalamocœle*, mihi).

(*b*) The adoption of Quain's name of *epencephalon* for the cerebellum (*Hinterhirn*), and of *metencephalon* for the medulla oblongata (*Nachhirn*). Huxley's term, *myelencephalon*, for the latter division, is rendered inconvenient, to say the least, from the fact that it is used by Owen to designate the entire cerebro-spinal axis. The fourth ventricle is called the *metacœle* (*myelocœle*, mihi), and the cerebellar ventricle the *epicœle* (*metacœle*, mihi).

(*c*) The word prosencephalon is used in the same sense as by Quain, *i.e.* as including the whole of the fore-brain proper (*Vorderhirn*). Both Owen and Huxley, on the other hand, use this term as synonymous with cerebral hemisphere, *i.e.* speak of paired prosencephala. In correspondence with this, the entire cavity of the fore-brain is called the *prosocœle*, and the lateral ventricles themselves *procœles* (*prosocœles*, mihi).

(*d*) The unpaired cerebral rudiment of the embryo is distinguished as the *protocerebrum*.

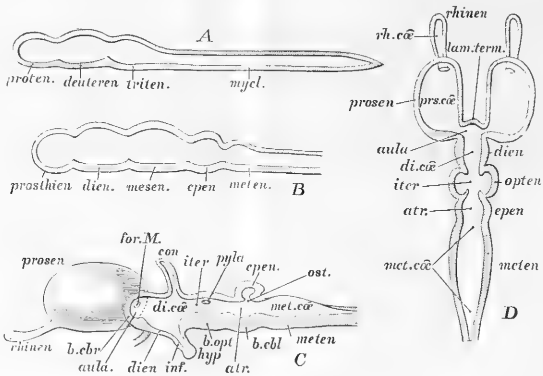

FIG. 1.—Diagrams showing three chief stages in the development of the nervous system. A, the *neuron* is divided into *myelon* and *encephalon*, the latter being again divided into the three primary vesicles, *protencephalon*, *deuterencephalon*, and *tritencephalon*. Similarly, the *neurocœle*, or general cavity of the neuron, is divided into *myelocœle* and *encephalocœle*, and the latter, again, into *proto-*, *deutero-*, and *trito-cœles*. B, the brain now consists of five encephalomeres, the *prosthi-*, *di-*, *mes-*, *ep-*, and *met-encephala*, containing respectively the *prosthio-*, *dia- meso-*, *epi-*, and *meta-cœles*. C, D, the brain has assumed its permanent form, and is shown in C in vertical, in D in horizontal section The prosthiencephalon has sent out paired prosencephala, a small unpaired portion, the *basicerebrum* (*b.cbr*), being left, the latter being bounded in front by the lamina terminalis (*lam.term*) Each prosencephalon has further given rise to a *rhinencephalon*. Similarly, the prosthiocœle now consists of unpaired *aulæ* and of paired *proso* and *rhino-cœles* (*prs cœ*, *rh.cœ*), the former communicating with the aula by the foramina of Monro, or portæ (*for.M.*). The diacœle is continued above into the conarium (*con*), below into the infundibulum (*inf*) with the hypophysis (*hyp*). The mesencephalon consists of an unpaired ventral *basi-opticus* (*b.opt*), and of paired *optencephala*; its cavity of a median *iter*, and of paired *optocœles*, which communicate with the iter by the *pylæ*. The epencephalon is divided into a dorsal portion, the cerebellum, or epencephalon proper, and a ventral division, the *basi-cerebellum* (*b.cbl*), containing a cavity, the *atrium* (*atr*), which communicates with the epicœle proper, or cavity of the cerebellum, by the *ostium* (*ost*). The metencephalon and metacœle (*met.cœ*) have undergone but little alteration.

(*e*) The unpaired portion of the fore-brain, left by the budding-off of the cerebral hemispheres, is not specially named, but its cavity is termed the *aula*. This is a large and distinct cavity in some sharks (*e.g. Scymnus*, Fig. 2), but in the higher forms becomes the Y-shaped passage between the third and the lateral ventricles. This passage is sometimes spoken of as the "foramen of Monro," but the latter term is more correctly applied to the aperture between each of its anterior limbs and the corresponding lateral ventricle: this aperture Wilder calls the *porta*.

(*f*) The specialised cavities in the optic lobes of Amphibia and Sauropsida are called *optocœles*, the name *iter* (abbreviation of "iter a tertio ad quartum ventriculum") being retained for the unpaired portion of the *mesocœle* or entire cavity of the mid-brain. The iter communicates with each optocœle by a small aperture, the *pyla*. No name is given to the ventral portion of the mesencephalon after formation of the optic lobes, *i.e.* the part usually known by the awkward plural designation *crura cerebri*.

(*g*) The ventral portion of the epencephalon, the fibres of which become the pons Varolii in mammals, is called the *præ-oblongata*, the word *post-oblongata* being used as a synonym for metencephalon or medulla oblongata in the restricted sense.

(*h*) The entire cerebro-spinal axis is called the *neuron*, its cavity the *neurocœle*.

(*i*) The name *encephalocœle* is applied to the entire system of brain-cavities, or to the single cavity of the undivided embryonic encephalon.

(*k*) The name *myelocœle* is applied to the central canal of the myelon. This cavity is also distinguished into a lumbar dilatation, the *rhombocœle* (sinus rhomboidalis) and a contracted portion, the *syringocœle*.

[1] "Notes on the Anatomy and Embryology of *Scymnus lichia*," *Trans. N.Z. Inst.* xv. (1882), p. 222; "A Course of Instruction in Zootomy," London, 1884

[2] "Encephalic Nomenclature," *New York Medical Journal*, xli. (1885), pp. 325 and 354.

This scheme I propose to modify in certain particulars. For the sake of clearness I give diagrams (Fig. 1) showing three important stages in the development of the brain, as well as drawings of the brain of *Scymnus lichia* (Fig. 2). The latter shows with such diagrammatic clearness the typical structure of the Vertebrate encephalon that I now always use it as a starting-point for the study of that organ in my lectures.

(*a*) I propose to follow Wilder in his use of the words neuron and neurocœle, encephalon and encephalocœle, myelon and myelocœle (Fig. 1, A). The words syringocœle and rhombocœle appear to me unnecessary: I prefer to say that in some Vertebrates (*e.g.* birds) the lumbar region of the myelocœle is dilated into a sinus rhomboidalis.

(*b*) The three primary cerebral vesicles may be called respectively the *protencephalon*, *deuterencephalon*, and *trit·ncephalon*; their cavities the *protocœle*, *deuterocœle*, and (primary) *tritocœle* (Fig. 1, A).

(*c*) In what may be called the sub-primary stage of segmentation, the anterior, or first, and the posterior, or third, cerebral vesicles have each divided into two parts, the brain thus consisting of

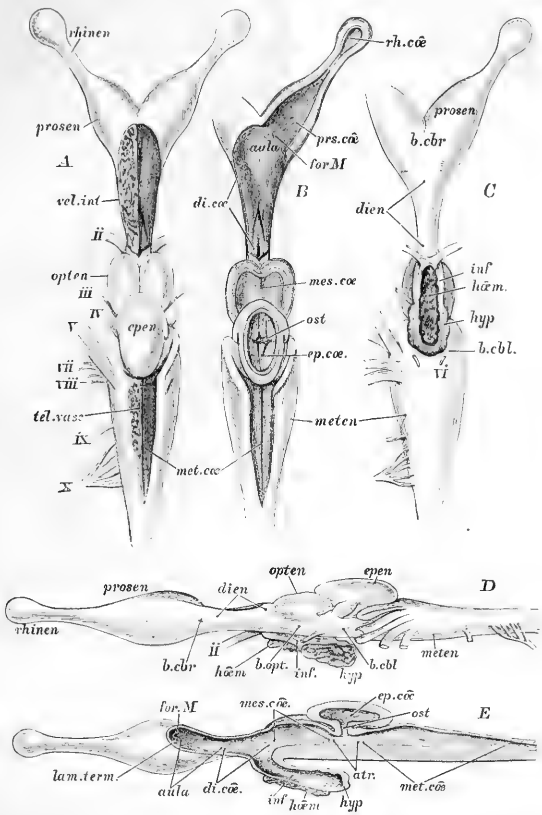

FIG. 2.—Five views of the brain of *Scymnus lichia* (nat. size). A, dorsal view of the brain, entire, save for the removal of the velum interpositum (*vel.int*) and tela vasculosa (*tel.vasc*) on the right side. B, the same, with the cavities opened from above. C, the entire brain from below. D, the entire brain from the left side. E, longitudinal vertical section. The letters have the same significance as in Fig. 1, except *hæm*, hæmatosac (saccus vasculosus); *vel.int*, velum interpositum; *tel.vasc*, tela vasculosa; and *ii–x*, cerebral nerves.

five encephalomeres, which I propose to call respectively the *prosthiencephalon* (= prosencephalon of Quain, *Vorderhirn*) and *diencephalon* (= thalamencephalon), derived from the protencephalon; *mesencephalon* (identical with the deuterencephalon), *epencephalon*, and *metencephalon*, formed by the constriction of the primitive tritencephalon. The cavities of these five brain-segments will be the *prosthio-*, *dia-*, *meso-*, *epi-*, and *meta-cœles* (Fig. 1, B).

(*d*) In the next stage of differentiation of the fore-brain, the prosthiencephalon gives rise dorsally to the two cerebral hemispheres: I propose to follow Owen and Huxley in calling them the *prosencephala* (Fig. 1, C and D; Fig. 2, A—E, *prosen*); their cavities, or lateral ventricles, being named *prosocœles* (*prs.cœ*). The median portion of the prosthiencephalon, after separation of the prosencephala, may be called the *basicerebrum* (*b.cbr.*); its cavity, the *aula*, is Y-shaped, communicating by its unpaired posterior limb with the diacœle, by its paired anterior limbs with the prosocœles through the *foramina of Monro* (*for.M*), or *portæ*. The two prosencephala may be spoken of collectively by the old name, *cerebrum*, which, as Pye-Smith remarks,[1] "ought to be strictly limited to the hemispheres with the corpus callosum, corpora striata, and fornix."

[1] "Suggestions on some Points of Anatomical Nomenclature" *Journ. of Anat. and Phys.*, xii. (1878), p. 154.

From each prosencephalon is budded off an olfactory lobe or *rhinencephalon*, containing a cavity, the *rhinocœle*, and usually divisible into a stem-like portion, or *crus*, and a dilated extremity, or *bulb*.

(*e*) The mesencephalon becomes differentiated dorsally into the paired optic lobes, or *optencephala*, the cavities of which, or *optocœles*, are frequently clearly distinguishable from the remaining median portion of the mesocœle, or *iter*, with which they communicate by small apertures, the *pylæ*. In many fishes, however, although the optic lobes are well formed, the mesocœle shows no distinction into iter and optocœles (cf. Fig 2, B and E). The unpaired ventral portion of the mid-brain, which in the lower forms shows no differentiation into crura cerebi may be distinguished as the *basi-opticus*.[1]

(*f*) In the epencephalon the dorsal region grows out into the cerebellum, or epencephalon proper, its ventral region, or *basi-cerebellum* (præ-oblongata, Wilder), being usually quite indistinguishable from the metencephalon, but becoming marked off in the Mammalia by the development of the pons. The anterior portion of the fourth ventricle of the adult, *i.e.* the portion corresponding to the basi-cerebellum, is of course epencephalic and not metencephalic, and may be distinguished as the *atrium* (Fig. 1, C and D; Fig. 2, E): it communicates, in Selachians, with the epicœle proper, or cerebellar ventricle, by a small aperture, the *ostium* (Fig. 2, B and E, *ost.*).[2]

It will be noticed that a mixture of Latin and Greek names occurs in the above scheme. This has been adopted so as to interfere as little as possible with the names in common use and with those proposed by Wilder. The Latin names, moreover, are introduced with a certain consistency; *e.g.* the basi-cerebrum is the median unpaired portion of the protencephalon, the basi-opticus of the mesencephalon, and the basi-cerebellum of the epencephalon; similarly, the cavities of these basal regions are respectively the aula, the iter, and the atrium, the main "ventricles" being all distinguished by names of Greek origin.

The advantages claimed for the proposed nomenclature are the following:—

(*a*) Names are given to important structures which have hitherto been designated by more or less lengthy phrases, *e.g.* basi-cerebrum, aula, mesocœle, &c.

(*b*) The systematic brain-nomenclature of Quain is brought up to date by introducing changes rendered desirable by the progress of animal morphology.

(*c*) The cavities of the brain are distinguished by systematic names which have an evident connection with those of the encephalomeres themselves, instead of by names which have no relation either with the regions of the brain in which the cavities occur, or with one another.

(*d*) The description of the nervous system of the lower Chordata is simplified. For instance, in *Amphioxus*, one may say that the neuron shows no distinction externally into encephalon and myelon, but that the neurocœle is dilated anteriorly into a small encephalocœle.

While agreeing with Prof. Wilder in the advisability of making the changes proposed above in the nomenclature of the central nervous system, I differ from him in failing to see the necessity, or, indeed, the desirability, of making all binomial names monomial. Such names, for instance, as anterior commissure, corpus callosum, lamina terminalis, which are not misleading, and which do not require to be connected with homologous parts by a consistent nomenclature, may very well be left alone; although, if one could start *ab initio*, I quite admit that the substitutes proposed by Wilder might be preferable. In any case, however, his name *pseudocœle* is thoroughly deserving of adoption as a substitute for the misleading appellation, "fifth ventricle."

Prof. Wilder's suggestion that *encephalon* should be Anglicised into *encephal* is worthy of consideration, especially as the word ought to be written *encephalos*, and it would be an advantage to get rid of the incorrect neuter termination. I have adopted the abbreviated form in the following table, which shows at a glance the nature of the proposed scheme of nomenclature. The names of the various divisions of the nervous system are printed in capitals, those of the corresponding cavities in italics.

NEURON *Neurocœle*	ENCEPHAL *Encephalocœle*	PROTENCEPHAL *Protocœle*	PROSTHIENCEPHAL *Prosthiocœle*	RHINENCEPHALS *Rhinocœles*
				PROSENCEPHALS (CEREBRUM) *Prosocœles*
			DIENCEPHAL *Diacœle*	BASI-CEREBRUM *Aula*
		DEUTERENCEPHAL *Deuterocœle*	MESENCEPHAL *Mesocœle*	OPTENCEPHALS (OPTIC LOBES) *Optocœles*
				BASI-OPTICUS *Iter*
		TRITENCEPHAL *Tritocœle*	EPENCEPHAL *Epicœle*	EPENCEPHAL (CEREBELLUM) *Epicœle* (definitive)
				BASI-CEREBELLUM *Atrium*
			METENCEPHAL *Metacœle*	
	MYELON *Myelocœle*			

My object in writing this note is not so much to get my own or any other system of names adopted, as to urge the necessity for a reform in the nomenclature of the central nervous system and its cavities—a necessity which no comparative anatomist, especially if he be a teacher, can fail to see. Recent investigations of the skull, shoulder-girdle, urinogenital organs, &c., of Vertebrates have necessitated corresponding changes in nomenclature, and similar changes are constantly being made among the various Invertebrate groups. It would certainly be a great boon, both to teachers and students, if a like reform could be generally adopted for the Vertebrate nervous system.

Dunedin, N.Z., September 15 — T. JEFFERY PARKER

1 "Critics will no doubt object to using an adjective as a substantive, but how far this is admissible is entirely a matter of usage," &c. (Pye-Smith, *loc. cit.*, p. 174, note).

2 *Cerebellum* is one of the few names in the older brain-nomenclature which presents no ambiguity, so that the only reason for giving it a Greek synonym is the logical satisfaction of having a similar set of names for all the great divisions of the brain. Strictly speaking, the word epencephalon, being synonymous with *cerebellar segment*, ought not to be used for the cerebellum itself, and *hyperencephalon* might be used instead, with *hyperocœle* for cerebellar ventricle.

THE IMPERIAL INSTITUTE

THE following is the report of the Committee appointed by H.R.H. the Prince of Wales to prepare a scheme for the proposed Imperial Institute:—

The committee appointed by your Royal Highness to frame a scheme for an Imperial Institute intended to commemorate the fiftieth year of Her Majesty's reign beg leave to submit to your Royal Highness the following report.

They do not fail to remember that the scheme which your Royal Highness indicated in your letter of September 13 last to the Lord Mayor of London had its origin in the remarkable interest excited by the recent Exhibition, by which not only the material products, resources, and manufactures, but the loyal feeling of the great colonies and possessions of Her Majesty's Empire, were illustrated in a most signal manner.

The object, therefore, which naturally suggested itself first to the committee was the development, with some necessary modifications, of your Royal Highness's idea of creating a permanent representation of the resources and progress of the colonies and India.

On pursuing, however, the consideration of the subject, the committee became persuaded that a memorial really worthy of the jubilee year of Her Majesty's reign could not be confined in its objects to any one part or parts of Her Majesty's Empire, and that it must in some form and degree also comprehend a representation of the United Kingdom.

Their desire, therefore, in the following outline of the scheme which they recommend is to combine in a harmonious form, and with a view to some practical and useful purpose, a representation of the colonies and India on the one hand and of the United Kingdom on the other.

They submit that this object will be best indicated by giving to the memorial the title of The Imperial Institute of the United Kingdom, the Colonies, and India.

They think that the Institute should find its home in buildings of such a character as worthily to commemorate the jubilee year of the Queen's reign, and to afford accommodation suitable for an institution combining the important objects which they now proceed to describe.

It is obvious that several departments of the Institute, such as the hall, conference rooms, &c., which will be found described under the Colonial and Indian Section and the United Kingdom Section respectively, will be common both to the colonies and India and to the United Kingdom: but as others have special relation to a particular portion of Her Majesty's dominions, it will be found convenient to make the following division.

A. *Colonial and Indian Section.*—The object of the Colonial and Indian Section will be to illustrate the great commercial and industrial resources of the colonies and India, and to spread a knowledge of their progress and social condition.

To this end provision should be made for—

(1). The display in an adequate manner of the best natural and manufactured products of the colonies and India, and in connection with this the circulation of typical collections throughout the United Kingdom.

(2). A hall for the discussion of colonial and Indian subjects, and for receptions connected with the colonies and India.

(3). The formation of colonial and Indian libraries, and establishing in connection therewith reading, news, and intelligence rooms.

(4). The incorporation in some form into the proposed Institute of the Royal Colonial and Royal Asiatic Society, if, as is hoped, it be possible to bring about such a union.

(5). The collection and diffusion of the fullest information in regard to the industrial and material condition of the colonies, so as to enable intending emigrants to acquire all requisite knowledge. Such information might be advantageously supplemented by simple and practical instruction. An emigration office of this character should be in correspondence with the provincial towns, either through the free libraries or by other means, so that information may be readily accessible to the people. These objects would be greatly facilitated if, as may be hoped, the Government should consent to the transfer to the buildings of the Institute of the recently formed Emigration Department, which would, by a close connection with the Institute, largely increase its usefulness.

Facilities might be afforded for the exhibition of works of colonial and Indian art.

It is also considered desirable that means should be provided, not for a general exhibition, but for occasional special exhibitions of colonial and Indian produce and manufactures. At one time a particular colony or portion of the Empire may desire to show its progress; at another time a general comparison of particular industries may be useful. Whilst the permanent galleries would exhibit the usual commercial or industrial products of the several colonies and India, the occasional exhibitions would stimulate and enlist the sympathies of colonial and Indian producers, and keep up an active co-operation with the industrial classes of this country.

B. *United Kingdom Section.*—The leading objects of this Section will be to exhibit the development during Her Majesty's reign and the present condition of the natural and manufactured products of the United Kingdom, and to afford such stimulus and knowledge as will lead to still further development, and thus increase the industrial prosperity of the country.

We submit that these objects may be carried out by making provision for the following purposes:—

(1). Comprehensive collections of the natural products of the United Kingdom, and of such products of other nations as are employed in its industries, with full scientific, practical, and commercial information relating thereto.

(2). Illustrations of manufactured products, typical of their development and present condition, of trades and handicrafts, and their progress during the Queen's reign, including illustrations of foreign work when necessary for comparison; together with models illustrating naval architecture, engineering, mining, and architectural works.

(3). A library for industrial, commercial, and economic study, which should contain standard works and reports on all subjects of trade and commerce. It will be desirable also to include a library of inventions of the Empire, and, as far as possible, of the United States and other countries.

(4). Reading and conference rooms supplied with English, colonial, and foreign commercial and technical periodicals, and a fully-equipped map room for geographical and geological reference. The conference rooms would be of value for meetings of Chambers of Commerce and other bodies of a kindred nature.

(5). The promotion, in affiliation with the Imperial Institute, of commercial museums in the City of London and in the commercial centres of the provinces. To these the Institute would contribute specimens, samples, and exhibits of the commercial products likely to be specially valuable in particular localities. There should also be an organisation to connect the Imperial Institute with the provincial centres by lectures, conferences, the circulation of specimens, and other means.

It is hoped that the Institute may lead to the organisation of high schools of commerce, such as are now established in the chief commercial towns of most Continental countries, but which have, as yet, unfortunately no existence in the United Kingdom.

(6). The building will also advantageously afford accommodation for (*a*) comparing and examining samples by the resources of modern science, and (*b*) the examination of artisans under the various schemes already existing for the promotion of technical education.

Space should also be provided for occasional exhibitions of separate industries, or of the special industries carried on in great provincial centres: for example, there might at one time be an exhibition of iron manufactures, at another of pottery, at another of textile fabrics, &c., which would tend to stimulate improvement in the different departments of industrial life. This object might be assisted by separate exhibitions of the handiwork of artisans.

The committee, having detailed the general nature of their suggestions under these heads, desire to add that they do not anticipate the exhibits in the collections remaining unchanged. They contemplate that as improvements are made from time to time the later and better results would displace those out of date.

They have had to consider how the space should be distributed between the United Kingdom on the one hand and the colonies and India on the other, and they recommend that whatever portion of the buildings is not required for purposes manifestly common to both should be allotted to the two sections fairly in equal parts.

C. *Government of Institute.*—The committee recommend that a new body, entirely independent of any existing organisation, should be created for the government of the Institute. This body should be thoroughly representative of the great commercial and industrial interests of the Empire. The colonies and India should have a fair share in the government of the Institute, and each colony should have special charge of its own particular department, subject, of course, to the general management of the entire institution.

The method of carrying this out would be prescribed by the Charter, after full consideration by Her Majesty in Council.

D. *Site.*—The committee, being fully conscious of the advantage of a central position for the Institute, have considered the various possible sites, and have, as far as has been within their power, obtained estimates of their cost.

To carry out the several objects which the committee have indicated, a large space is necessary. The committee have been unable to find any such suitable site in the central parts of London, except at a cost which, looking at the probable amount of subscriptions, would, after the purchase of the ground, leave a sum wholly inadequate for the erection and maintenance of the buildings, and for carrying out the objects of the Institute.

The site of about five acres recently secured for the New Admiralty and War Offices is valued at 820,000*l.*, or rather over 160,000*l.* per acre. That now vacant in Charles Street, opposite the India Office, is less than an acre, and would cost at least 125,000*l.*; probably another acre might be secured by private contract, so that the value of a limited site in this position would not be less than 250,000*l.* It has been suggested that a single acre not far from Charing Cross might be obtained for 224,000*l.* Two and a half acres on the Thames Embankment have been offered for 400,000*l.*; and it is stated that six acres might be procured from Christ's Hospital at 600,000*l.* Another good central position has been suggested, consisting of two and a half acres, which has been valued at 668,000*l.*

It is, of course, probable that these sites might be obtained at somewhat less than the prices asked, but, allowing for this, it is obvious that the purchase of any adequate area would involve the expenditure of a quarter to half a million.

The committee have therefore been forced to abandon the hope of obtaining a central site within the limits allowed by any probable subscription.

The attention of the committee was then drawn to the property at South Kensington belonging to the Commissioners for the Exhibition of 1851. This property was bought out of the profits of that Exhibition, with the express object of offering sites for any large public buildings which might be required for the promotion of science and art.

Under these circumstances, the committee submit to your Royal Highness that the Imperial Institute may well establish a claim for the grant of a site of sufficient magnitude on property bought and reserved for public institutions of this character.

Though sensible of the objections that may be urged against the situation at South Kensington, the committee think that the advantage must be obvious of obtaining a sufficient site virtually free of cost, so that the whole of the subscriptions may be devoted to providing a building for and establishing and maintaining the Institute.

The committee, while guided in the recommendation of a site by the considerations they have indicated, think it right to add that there are some incidental advantages connected with that at South Kensington.

In that locality are combined the City and Guilds Technical College, the Royal College of Music, and the Government Museums and Schools of Science and Art, which ought to be in immediate proximity to an Imperial Institute of the character which we have described.

The technical character of the collections and exhibitions of the Imperial Institute has a natural connection with the collections of science and art in the Government Museums.

E. *General Observations.*—An Imperial Institute for the United Kingdom, the Colonies, and India, would fail in its chief object if it did not constantly keep in view that it ought to be a centre for diffusing and extending knowledge in relation to the industrial resources and commerce of the Empire.

The necessity for technical education is now fully appreciated, because the competition of industry has become, in a great measure, a competition of trained intelligence. The committee, however, do not recommend that the Imperial Institute should aspire to be a college for technical education. Many of the large towns in Great Britain have recently established colleges or schools of science and art. The Imperial Institute might serve to promote technical education in these, and to unite them with colleges of larger resources which have been founded or formed branches for the purpose in the metropolis. It is too much to hope that an active co-operation of this character between the provincial centres and London could be at once undertaken by the Imperial Institute. But the committee bear in mind that, in their last report, the Commissioners of 1851 have indicated an intention to assist in carrying out such a scheme. If the Commissioners would contribute three or four thousand pounds annually, it would be possible to establish scholarships which might enable promising candidates of the working classes to attend the local institutions, and even, when it was desired, to complete their technical education in colleges of the metropolis. In addition to this aid, the Imperial Institute might be able, in other ways, to promote the foundation of scholarships both in connection with the colonies and provincial centres, in the hope of still further extending these benefits to the working classes.

In conclusion, the committee submit that an Imperial Institute such as they have sketched in broad outline would form a fitting memorial of the coming year, when Her Majesty the Sovereign of this Empire will celebrate the jubilee of her happy reign. It would be an emblem of the unity of the Empire, embracing as it does all parts of the Queen's dominions, and tending to promote that closer union between them which has become more and more desired. It would exhibit the vast area, the varied resources, and the marvellous growth, during Her Majesty's reign, of the British Empire. It would unite in a single representative act the whole of her people; and, since both the purpose and the effect of the Institute will be to advance the industrial and commercial resources of every part of the Empire, the committee entertain a confident hope that Her Majesty's subjects, without distinction of class or race, will rejoice to take part in offering this tribute of love and loyalty.
—HERSCHELL (Chairman), CARNARVON, REVELSTOKE, ROTHSCHILD, G. J. GOSCHEN, LYON PLAYFAIR, HENRY JAMES, HENRY T. HOLLAND, H. H. FOWLER, C. T. RITCHIE, FRED. LEIGHTON (President of the Royal Academy), ASHLEY EDEN, OWEN T. BURNE, REGINALD HANSON (Lord Mayor), J. PATTISON CURRIE (Governor of the Bank of England), JOHN STAPLES, FREDERICK ABEL (Vice-President of the Society of Arts), J. H. TRITTON (Chairman of the London Chamber of Commerce), NEVILE LUBBOCK, HENRY BROADHURST.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—At the annual election to scholarships and exhibitions in St. John's College, for candidates who have not yet commenced residence, the following awards were made:—

Foundation Scholarships: (80*l.*) to A. Vaughan, University College School, and H. Reeves, Surrey County School; (50*l.*) to O. W. Owen, Liverpool Institute (all for Mathematics); (60*l.*) to J. T. Hewitt, South Kensington School of Science, for Chemistry.

Minor Scholarships: (50*l.*) to G. T. Bennett, University College School, and W. J. Dobbs, Wolverhampton School, for Mathematics, and to R. A. Lehfeldt, for Physics.

Exhibitions to J. J. Alexander, Queen's College, Belfast, for Mathematics, and to F. F. Blackman, St. Bartholomew's Hospital, for Physiology and Botany.

SCIENTIFIC SERIALS

THE articles in the *Journal of Botany* for November and December are mostly descriptive. Mr. H. N. Ridley concludes his description of the Monocotyledonous plants collected in New Guinea by Mr. Forbes, including a number of new species; Mr. J. G. Baker, his synopsis of the Rhizocarpeæ, with a monograph of *Pilularia;* and Dr. Trimen, his valuable account of the flora of Ceylon and its relations to the climate of the island.—Mr. J. G. Baker describes some new species of Liliaceæ from the Cape of Good Hope.—The other original papers refer to the distribution of British plants.

Nuovo Giornale Botanico Italiano for October.—G. Venturi describes several species of moss new to the Italian flora, or rare or critical species.—L. Macchiati, on the extra-floral nectaries of the Amygdaleæ, describes nectariferous glands on the leaf-stalk of *Persica vulgaris, Cerasus vulgaris, Prunus domestica,* and *Amygdalus communis.* These agree in function with the extra-floral nectaries in other European plants, in serving as a protection against the attacks of caterpillars; while in the case of natives of Tropical America, their purpose is invariably to protect against the attacks of the ant *Oecodoma*, by attracting other ants, enemies to this species. The author records a diurnal periodicity in the amount of nectar exuded from the glands, which reaches its maximum early in the morning, its minimum in the afternoon.—B. Scortechini describes several new species of Scitamineæ from the Malayan peninsula, including a new genus, *Lowia*.—Prof. T. Caruel has a note on the fruit and seeds of the cacao.—P. Severino describes the variety *purpurea* of *Aceras anthropophora*, and the micro-chemical reactions of the purple cells.—Two teratological papers complete the list: on viviparity and prolification in *Spilanthes caulirrhiza*, by Dr. F. Tassi; and teratological notes (on *Aegle sepiaria*, *Lysimachia ephemerum*, and *Saxifraga crassifolia*), by C. Massalongo.

SOCIETIES AND ACADEMIES

London

Royal Society, December 16.—"On a Varying Cylindrical Lens." By Tempest Anderson, M.D., B.Sc. Communicated by Prof. A. W. Williamson.

The author has had constructed a cylindrical lens in which the axis remains constant in direction and amount of refraction, while the refraction in the meridian at right angles to this varies continuously.

A cone may be regarded as a succession of cylinders of different diameters graduating into one another by exceedingly small steps, so that if a short enough portion be considered, its curvature at any point may be regarded as cylindrical. A lens with one side plane and the other ground on a conical tool is therefore a concave cylindrical lens varying in concavity at different parts according to the diameter of the cone at the corresponding part. Two such lenses mounted with axes parallel and with curvatures varying in opposite directions produce a compound cylindrical lens, whose refraction in the direction of the axes is zero, and whose refraction in the meridian at right angles to this is at any point the sum of the refractions of the two lenses. This sum is nearly constant for a considerable distance along the axis so long as the same position of the lenses is maintained. If the lenses be slid one over the other in the direction of their axes, this sum changes, and we have a varying cylindrical lens. The lens is graduated by marking on the frame the relative position of the lenses when cylindrical lenses of known power are neutralised.

Lenses were exhibited varying from 0 to − 6DCy, and from 0 to + 6DCy.

Linnean Society, December 16.—W. Carruthers, F.R.S., President, in the chair.—H.R.H. the Prince of Wales was elected an Honorary Member of the Society.—Messrs. A. Bawtree, F. Justen, T. N. Mukharji, F. W. Oliver, and R. V. Sherring were elected Fellows, and G. Nicholson an Associate, of the Society.—The President announced that Sir George MacLeay, K.C.M.G., had presented to the Society a portrait of the late Rev. W. Kirby, the distinguished entomologist, and the manuscripts and correspondence of his father, Alexander MacLeay (elected F.L.S. 1794), formerly Secretary to the Society. For these acceptable donations, a special vote of thanks was accorded by the Fellows.—Prof. F. O. Bower exhibited a series of photographs illustrating the vegetation of Ceylon.—Mr. E. A. Heath showed a stormy petrel, *Procellaria pelagica*, which was picked up alive in Kensington Gardens on December 9; the bird evidently having been driven inland by the great storm of the previous day.—Mr. D. Morris drew attention to the fresh leaves, and the fibres extracted therefrom, of *Agave salmdyckia* and *A. Ixtli*.—Mr. W. T. Thiselton Dyer showed one of the volumes of "Honzo Zufu" ("Illustrations and Brief Descriptions of the Plants of Japan"), by Iwasatti Tsanemasa, which consists of ninety-six volumes containing 2000 coloured figures. Only two or three copies of this important botanical work are known to be complete, as a great part of it only exists in the original native hand-work.—The President exhibited a spike of maize from an ancient Peruvian grave, also samples of prehistoric wheat from ancient British and Romano-British burial-mounds in Wiltshire.—Mr. G. J. Romanes read a paper on the sense of smell in dogs, a report of which we hope to give in a future number.—Mr. C. T. Druery gave a communication on a new instance of apospory in *Polystichum angulare*, var. *pulcherrimum*. He infers that the formation of the prothallus is preceded by a very different series of phenomena from those already recorded. In the one case the prothalli are simple extensions of the cellular substance of the tips of the pinnules commencing at points quite beyond the venation, and produce no root-hairs unless brought into contact with the soil. In the other case, however, the prothallus is a direct outgrowth of the tip of a veinlet, and at once produces root-hairs in abundance long before it assumes any other characteristic of a prothallus, and finally the resulting prothallus is much thicker in substance.—A paper was read on apospory and allied phenomena, by Prof. F. O. Bower. The term "sporal arrest" is applied to all cases where such spores do not come to functional maturity. The arrest is often, but not always, followed by substitutionary or correlative vegetative growths: these take the form of buds, similar to the sporophyte which produced them, and then would be termed cases of "sporophytic budding"; but in other cases the correlative growths may assume the characters of the oophyte or prothallus. Where this happens, the phenomenon is termed "apospory." This direct transition from the sporophyte to the oophyte was *induced* some ten years ago in certain mosses, by Pringsheim and Stahl; and it is now described in detail in two ferns, an *Athyrium* and a *Polystichum*. Both plants were found some years ago growing wild, and the fact of the transition was recognised by Mr. Druery and Mr. Wollaston, and has been already published by the Linnean Society. The present paper describes these and similar phenomena in detail, and shows how in the *Polystichum* at least four different modes of origin of the oophytes may be distinguished, two being in connection with the sorus, while two are at points apart from the sorus, and may even occur on fronds which bear no sori at all. The latter part of the paper is occupied by comparing these phenomena with others already known in higher and lower plants. The general conclusion is that the whole phenomenon of apospory is to be regarded rather as a sport than as a reversion bearing deep morphological conclusions with it.

Chemical Society, December 2.—W. Perkin, F.R.S., Vice-President, in the chair.—Mr. Forbes Rickard was formally admitted a Fellow of the Society.—The following papers were read:—Bismuthates, by M. M. Pattison Muir and Douglas J. Carnegie.—The action of inorganic compounds on living matter, by James Blake, M.D.—Morindin and morindon, by T. E. Thorpe, F.R.S., and T. H. Greenall.—The hydration of salts: cadmium chloride, by S. U. Pickering.—The decomposition of sodium carbonate on fusion, by S. U. Pickering.—Derivatives of tolylbenzene, by Thomas Carnelley, D.Sc. (Lond.), and Andrew Thomson, D.Sc. (Edin.).—The amount of chlorine in rain-water collected at Cirencester, by Edward Kinch, Royal Agricultural College, Cirencester.—Some analogous phosphates, arsenates, and vanadates, by John A. Hall, student in the Laboratory of Owens College.—Agricultural experiments with iron sulphate as a manure during 1886, by A. B. Griffiths, Ph.D.

Royal Meteorological Society, December 15.—Mr. W. Ellis, F.R.A.S., President, in the chair.—Mr. G. R. Farncombe, B.A., Mr. C. E. B. Hewitt, B.A., and Capt. S. Trott were elected Fellows of the Society.—The following papers were read:—On the proceedings of the International Congress of Hydrology and Climatology at Biarritz, by Mr. G. J. Symons, F.R.S. This Congress was held in October, and was divided into three sections, viz. Scientific Hydrology, Medical Hydrology, and Climatology, Scientific and Medical. The total number of papers read was 109. An Exhibition was also held in connection with the Congress. The excursions were of primary importance to the medical men, and extended over a period of three weeks. The places visited were: Bayonne, Cambo, Dax, Arcachon, Pau, Eaux-Bonnes, Eaux-Chaudes, Cauterets, Lourdes, Bagnères-de-Bigorre, Luchon, Ussat, Ax, Montpellier, Cette, Boulou, Amélie-les-Bains, La Preste, Banyuls-sur-Mer, and Thues.—Report on the phenological observations for 1886, by the Rev. T. A. Preston, M.A., F.R.Met.Soc. The weather was, on the whole, very ungenial and everything much retarded; it was also very fatal to insect life, so that the complaints on this head have been far less than usual. Bush fruits were *very* abundant; strawberries and peas were spoilt by drought in many places; stone fruits, except plums, were not abundant; plums were extraordinarily plentiful, so much so that they realised nothing in the markets, the cost of picking and carrying often being more than they realised; apples were very poor, from the destruction of the bloom by heavy rain. Hay was good and plentiful, and well harvested; corn and other grain were not up to an average: root-crops were, as a rule, remarkably good.—A criticism of certain points of Prof. Langley's researches on solar heat, by Prof. S. A. Hill, B.Sc., F.R.Met.Soc. These experiments were carried out at Mount Whitney, in Southern California, during 1881.—Account of the hurricane of March 3-4, 1886, over the Fiji Islands, by Mr. R. L. Holmes, F.R.Met.Soc. This storm was the most destructive that has ever been known to occur in the Fiji group. The lowest barometer reading was 27·54 inches at Vuna, in Taviuni. The storm was accompanied by a great wave from 18 to 30 feet in height, which swept over the land and caused an immense amount of damage. It was reported that fifty vessels were wrecked and sixty-four lives lost during this hurricane.—Results of meteorological observations made at the Military Cemetery, Scutari, Constantinople, 1866-85, by Mr. W. H. Lyne. The annual mean temperature is 58°·4; the highest temperature registered was 103°·6 on June 22, and the lowest 13°·0, on January 25, both in 1869. The annual rainfall is 29·29 inches; the greatest fall in one day was 4·06 inches on September 25, 1866.

Physical Society, December 11.—Prof. McLeod, Vice-President, in the chair.—W. Natanson, Ed. Natanson, the Hon. R. Abercromby, Jul. Verteimer, and H. M. Elder were elected Members of the Society.—The following papers were then read:—On the influence of change of condition from the liquid to the solid state on vapour-pressure, by Prof. W. Ramsay, Ph.D., and Sydney Young, D.Sc., read by Dr. Young. The authors refer to some experiments published in *Wiedemann's Annalen*, vol. xxviii. p. 400, by W. Fischer, on the above subject, which show that the vapour-pressure of ice and solid benzene are less than those of water and liquid benzene at the same temperatures. By using the formula $p = a + bt + ct^2$ to express the relation between the pressure and temperature of saturated vapours, Fischer arrives at the absurd result that the vapour-pressure of liquid benzene is not identical with that of solid benzene at melting-point. If the above formula be replaced by $\log p = a + b\alpha t$, it is shown that the anomaly disappears. The authors have measured the vapour-pressures of solid and liquid benzene by the dynamical method, and obtain results agreeing closely with those of Fischer determined statically. They also calculate the vapour-pressure of solid benzene from that of the liquid, using the formula—

$$P_{t-1} = P - (P'_t - P'_{t-1})\left(\frac{V_{t-\frac{1}{2}} + F_{t-\frac{1}{2}}}{V_{t-\frac{1}{2}}}\right),$$

where P_t and P'_t are the vapour-pressures of the solid and liquid at temperature t, $V_{t-\frac{1}{2}}$ = heat of vaporisation of liquid, and $F_{t-\frac{1}{2}}$ = heat of fusion of solid at temperature $t - \frac{1}{2}$. The numbers so obtained are in accordance with those determined experimentally.—On the nature of liquids as shown by the thermal properties of stable and dissociable bodies, by the same authors, read by Prof. Ramsay. From experiments on the vapour-density and heat of vaporisation of stable and dissociable bodies, the authors arrive at two important results: (1) that for stable bodies, such as alcohol and ether, the density of their saturated vapours increases with rise of temperature, whereas for bodies such as acetic acid and nitric peroxide the vapour-density attains a minimum at a certain temperature, and increases with either rise or fall of temperature; (2) the heat of vaporisation of alcohol decreases with rise of temperature, but that of acetic acid attains a maximum at about 110° C., and decreases with rise or fall of temperature. From these results the authors seek to prove that the difference between stable liquids and their vapours consists in the relative proximity of the molecules, this proximity being greater in liquids than gases, and that the molecules of stable liquids are not more complex than those of their gases. Prof. Pickering dissented from this view, and thought that the molecules of liquids are aggregations or compounds of those of the gases. In answer to inquiries by the authors, Mr. Lewis Wright said that bodies which rotate the plane of polarisation of light when in the liquid state also rotate it in a proportionate degree when gaseous; and Capt. Abney remarked that stable liquids and their vapours give similar absorption-spectra, whereas those of dissociable bodies differ considerably. Both these facts seem to support the view put forward by the authors.—An account of Cauchy's theory of reflection and refraction of light, by Mr. James Walker, M.A. This paper is intended as a statement of the work previously done in the subject, and gives references to the original papers and "reproductions," &c., which will be of great value to persons studying this important branch of the theory of optics.—Mr. Shelford Bidwell exhibited and described a voltaic cell, in which the electrolyte is dry peroxide of lead. It consists of carefully dried peroxide placed between plates of lead and sodium, and gives a comparatively strong current, which passes from the sodium to the lead within the cell.

CAMBRIDGE

Philosophical Society, November 8.—Mr. Trotter, President, in the chair.—The following communications were made:—On the cœlum and body-cavity of Peripatus and the Arthropoda, by Mr. A. Sedgwick.—Note on the "vesicular vessels" of the onion, by S. H. Vines, M.A. Christ's, and A. B. Rendle, St. John's. In investigating the vesicular organs with the object of determining whether or not the transverse walls are perforated so as to place the cavities of successive segments in communication, the authors observed that, in the quiescent winter condition of the bulb, there are patches of callus—easily made conspicuous by staining with corallin—on the transverse walls. From this they infer that the transverse walls are perforated, the canals through them being open in the active, and closed by callus in the quiescent, condition of the bulb, just as is the case with sieve-tubes. This inference has, however, to be confirmed by an investigation of the bulb in the active condition. The authors also observed that each segment of a vesicular vessel contains a large nucleus.—On *Epiclemmydia lusitanica*, a new species of Alga, by Mr. M. C. Potter. During August and September, the author, with assistance from the Worts Travelling Scholars' Fund, investigated the life-history of a new species of Alga, now named *Epiclemmydia lusitanica*, which lives on the backs of the tortoises inhabiting the pools of Southern Europe. This Alga, which to the naked eye appears as small green roundish patches, is found to consist of a number of cells closely applied to tortoise-shell, but which are only a few layers deep, here and there penetrating into the tortoise-shell and causing it to flake off. The cells next to the tortoise-shell always force their way into any available crack, where they divide, and thus penetrate to some depth into the shell of the tortoise, and finally cause it to be flaked off. The Alga is reproduced by means of zoospores formed in the external layer of cells. These zoospores are all exactly similar, and swim about for a considerable time, after which they come to rest and germinate.—On a peculiar organ of *Hodgsonia heteroclita*, by Mr. Walter Gardiner. The author gave some account of the gland-bearing organs which are found in *Hodgsonia*—one in the axil of each of the foliage leaves. A study of the development of these organs demonstrates that they are peculiarly modified leaves, or rather bracts, since they are associated with the rudimentary flower-bud. They are doubtless identical with the similarly modified bracts which occur in connection with the fully developed flowers. The glands are found on the lower surface of the bract, and belong to the same type as those of *Luffa*, although of a distinctly higher order. Glands of a similar nature also occur on the under surface of the foliage leaves and on the sepals. The substance secreted by the glands is most probably of the nature of nectar, and the whole structures are to be regarded as extra floral nectaries. Having shortly described their histology, the author proceeded to make some remarks upon their function. A careful survey of the various gland-bearing genera of the *Cucurbitaceæ* and *Passifloraceæ*, and a comparison of such cases as those presented by *Passiflora quadrangularis* and *Passiflora fœtida*, placed it, in his opinion, beyond doubt that the function of the extra floral nectaries of the two orders is to attract certain insects—probably ants—which are of service to the plant in protecting it from the attacks of other and harmful insects, such as caterpillars, which are accustomed to creep up the narrow stem for the purpose of devouring or otherwise injuring the young growing shoots. As regards the fertilisation of *Hodgsonia*, the author showed that there were special contrivances to prevent the animal which fed upon the nectar of the flower from obtaining that of the extra floral nectaries, and *vice versâ*, and stated that, considering all the circumstances of the case, it was exceedingly probable that fertilisation was accomplished through the agency of a large night-flying moth.

EDINBURGH

Royal Society, December 20.—Sir W. Thomson, President, in the chair.—The Chairman communicated a paper, by the Rev. J. H. Sharpe, on a remarkable case of stream-lines in two-dimensional fluid motion. The body which produces the stream-lines is symmetrical about an axis, and consists of a semicircular head, with another portion the form of which is given by a transcendental equation.—A note on knots, by Mr. A. B. Kempe, was communicated by Prof. Tait. This paper is preliminary to a detailed investigation of knots by an entirely new process.—Sir W. Thomson discussed the ring-waves produced by throwing a stone into water. This investigation constitutes an extension of Poisson's and Cauchy's results. The wave-velocity is directly proportional to the square root of the wave-length, and the group-velocity is one half of the wave-velocity. —Sir W. Thomson also gave an investigation of the waves produced by a ship advancing uniformly into smooth water. His results show that there is practically no disturbance of the surface outside lines drawn from the ship making an angle of 19° 28′ on either side with the direction of motion. When tested by experiment the angle obtained was 19° 13′.—Dr. T. Muir communicated a paper, by Mr. P. Alexander, on the expansion of functions in terms of linear, cylindric, and spherical, &c., functions by a new and very general method.—In a paper on even distribution of points in space, Prof. Tait replied to certain criticisms made on his results regarding the foundations of the kinetic theory of gases.

MANCHESTER

Literary and Philosophical Society, November 2.—Prof. Osborne Reynolds, LL.D., F.R.S., Vice-President, in the chair.—The following papers were read:—Measurements of the magnetic induction and permeability in soft iron, by H. Holden, B.Sc.—The action of hydrochloric acid gas upon certain metals, by J. B. Cohen, Ph.D., F.C.S.—Capillary constants of benzene and its homologues occurring in coal-tar, by J. B. Cohen, Ph.D., F.C.S., all communicated by Dr. A. Schuster, F.R.S.

SYDNEY

Linnean Society of New South Wales, October 27.—Prof. W. J. Stephens, F.G.S., President, in the chair.—The following papers were read:—Catalogue of the described Coleoptera of Australia (part vi.), by George Masters. The present part contains all the known Scolytidæ, Brenthidæ, Anthribidæ, Bruchidæ, and Cerambycidæ of Australia, making the total number of species catalogued up to the present time, 6231. The next part, which will be published early in next year, will complete the Coleoptera.—Descriptions of new Lepidoptera, by E. Meyrick, B.A., F.E.S. In this paper descriptions are given of sixteen new species of Australian Lepidoptera belonging to fourteen genera, of which six are new. Among them is *Thalpochares coccophaga*, of which, at the December meeting of the Society, Mr. Masters exhibited specimens of both moths and larvæ, and called attention to the singular habits of the latter, which feed on a species of Coccus infesting a Macrozamia, living concealed in a cocoon-like shelter formed of the exuviæ of the Coccus, and finally pupating therein.—On the flowering seasons of Australian plants, by E. Haviland, F.L.S. This paper enumerates 113 species of plants observed in flower in the neighbourhood of Sydney during the month of July of this year, and is intended to be the first of a series of papers on the subject, by means of which it is hoped that the flowering seasons of at least the plants of the county of Cumberland will eventually be recorded.—Notes on the Rutaceæ of the Australian Alps, by James Stirling, F.G.S., F.L.S. Fourteen species of Rutaceous plants are enumerated as occurring in the region of the Australian Alps, of which one belongs to the genus Zieria, two to Boronia, nine to Eriostemon, and two to Correa. Remarks are also made upon the climatic and other conditions under which the plants occur, and the origin of their specific differences.—On a probably new species of tree-kangaroo from North Queensland, by C. W. De Vis, M.A. The name of *Dendrolagus bennettianus* is proposed for a supposed new species of tree-kangaroo of which one specimen was obtained in the Daintree River District. It lived in captivity for a time, but was subsequently killed, and its skin, unfortunately deprived of everything else but the bones of the hands and feet, was subsequently submitted to Mr. De Vis, who, after comparing it with two skins of *D. lumholtzi*, Collett, has no doubt that it is distinct from its compatriot, and is more nearly allied to *D. dorianus*, Ramsay. As full a description as is possible under the circumstances is given in the paper.—Dr. Ramsay exhibited a specimen of an apparently new species of Monacanthus, presented to the Australian Museum by Mr. G. R. Eastway. He also exhibited eggs of *Ptilonorhynchus violaceus* and *Rhynchæa australis*, and read notes on the subject.—Mr. A. J. North exhibited eggs of *Menura victoriæ*, Gould, from South Gippsland, and of *Geronticus spinicollis*, Jameson, from Hillston, N.S.W.—Mr. Whitelegge exhibited some magnificent specimens of the Alga *Claudea Bennettiana*, Harvey, hitherto known only from one small specimen. It was found abundantly near the Heads of Port Jackson during a recent trawling excursion in connection with the Australian Museum. Some of the specimens taken were nearly 1 foot in diameter. Mr. Whitelegge also exhibited a fine specimen of *Eozoon canadense*, and slides of it and of the above-mentioned Alga under the microscope.

PARIS

Academy of Sciences, December 20.—M. Jurien de la Gravière, President, in the chair.—Addendum to the note of December 6 on the conditions determining the form and density of the earth's crust, by M. Faye. In reply to M. de Lapparent's further objections to his theory, the author gives more detailed explanations regarding the phenomenon of compensation between land and water, pointing out that to this compensation is due the persistence of the original ellipsoidal figure of the globe.—On the phosphorescence of alumina, by M. Edmond Becquerel. The experiments here described point to different conclusions from those recently arrived at by M. Lecoq de Boisbaudran, while confirming those deduced from the author's earlier researches.—On some dispositions by means of which bi-refractive photometers may be realised without polarising the light, by M. A. Cornu. Without dispensing with the simpler apparatus of geometrical optics, the author describes several re-adjustments, which enable him to obtain double images of variable intensity in accordance with a well-known law, without having recourse to the employment of polarised light.—Remarks on M. Hugoniot's notes on the flow of gases, published in the *Comptes rendus* of November 15 and 22, by M. G. A. Hirn. The author replies briefly to the objections urged against his conclusions by M. Hugoniot, and still rejects the kinetic theory of gases, which he persists in regarding as one of the most fatal errors of modern science.—Observations in reference to Dr. Philip Paulitschke's "Researches on the Ethnography and Anthropology of the Somali, Gallas, and Hararis," by M. de Quatrefages. These observations, accompanying presentation of a copy of Dr. Paulitschke's work to the Academy, dwell especially on the great scientific interest presented by the mixed Negroid populations of Eastern Africa to the student of anthropology. These peoples are regarded as the outcome of an extremely ancient crossing between the Negro and the White races, the latter being represented chiefly by the African Semites.—Considerations on deep-sea fishes, and especially on those belonging to the sub-order Abdominalidæ, by M. Léon Vaillant. These remarks have special reference to the captures made by the *Talisman* Expedition, which included no less than 3800 true fishes, and which, combined with the researches of Günther, Gill, Cope, Goode, and Bean, already supply materials for a rough classification of these marine Vertebrates.—On the copper present in the grapes and wines yielded by vines treated with various cupreous preparations against mildew, by MM. U. Gayon and Millardet. These researches seem to show that, while the different processes generally exercise some influence on the quantity of copper contained in the grape and vinous fermentation, they appear to have none at all on the quantity of copper which remains in the wine after fermentation. The clear wine, after perfect clarification, contains no appreciable quantity of the metal.—Volume, absolute heat, and specific heat of saturated vapours, by M. Ch. Antoine. Taking a special zero for each vapour, simple formulas are established for working out these several volumes.—Note on the Abelian functions, by M. Appell.—On angular acceleration, a problem of pure kinematics, by M. Ph. Gilbert.—On the flow of elastic fluids, by M. Hugoniot. The author here applies to the flow of saturated aqueous vapour the same method already employed by him in the study of the flow of permanent gases.—Apparatus showing the two modes of reflection of a vibratory movement, by M. J. Violle. The apparatus here described has been constructed by M. König, and is perfectly adapted for demonstrating the method employed by Regnault in his great work on the measurement of the velocity of sound.—On some new properties, and on the analysis, of the pentafluoride gas of phosphorus, by M. H. Moissan. Having already indicated a new process for preparing this substance, the author here gives some fresh results terminating his researches on the phosphorated compounds of fluor.—On the relations of the efflorescence and deliquescence of the salts with the maximum tension of the saturated solutions, by M. H. Lescœur. The conditions of the efflorescence and deliquescence of the salts as determined by Debray are here brought into relation with the maximum tension of the saturated solutions.—Heat of formation of the methylate and ethylate of potassa, by M. de Forcrand.—On the wines and brandies extracted from strawberries and raspberries, by M. Alph. Rommier. By the process here described raspberries are made to yield a wine with over 18 per cent. of alcohol instead of the normal 2 or 2·5 per cent., while the brandy distilled from it retains a highly aromatic flavour. A still more palatable wine, with 16 per cent. of alcohol, is obtained from the fine strawberries grown in the neighbourhood of Paris, the corresponding brandy also preserving the flavour of the fruit.—On the zymotic properties of certain virus: fermentations of nitric substances under the influence of non-aërial virus, by M. S. Arloing. The object of this communication is to show that the virus of non-aërial microbes stimulates the fermentation of albuminoid substances.—Note on the multiplication of *Leucophrys patula*, Ehrenberg, by M. E. Maupas. In a favourable medium, a single individual of these Infusoria, which multiply by fissiparity, is found to increase to over a million in five days. Certain hitherto unobserved irregularities in the process of segmentation are here described.—On the phosphorescence of the Geophili, by M. Macé. As studied on a *Geophilus simplex*, Gervais, this phenomenon appears to be analogous to that of certain Chetopteræ described by Panceri and Jourdan.—On the typical nervous system of the dexter and sinister Prosobranchæ, by M. E. L. Bouvier.—Fresh anatomical and physiological studies on the Glyciphagi, by M. P. Mégnin.—The diseases of the olive, by M. L. Savastano. A brief description of the various forms of hyperplasia and tumours by which this plant is affected.—Remarks on the so-called Calcifugal vegetation, by M. Ant. Magnin. A theory is advanced to explain the presence of these plants in the limestone region of the Jura.—On two rocks in the Vélay and Lyons districts, containing beryl and apatite, by M. Ferdinand Gonnard.—On an experiment undertaken to determine the direction of the currents of the North Atlantic, by Prince Albert of Monaco. The author describes a second excursion on board the *Hirondelle*, during which 510 bottles were thrown into the sea along a course about 500 miles long, and nearly parallel with the twentieth meridian west of Paris. The operation was begun on August 29 and completed on September 5, 1886, and some of the floats have already been picked up at various points on the European seaboard; but the general results are reserved for a future communication.—The periodical showers of shooting-stars and the seismic disturbances of the years 1883, 1884, and 1885, by M. Ch. V. Zenger. During these years, both orders of phenomena are shown to coincide, while they are also frequently accompanied by hurricanes, cyclones, electric discharges, and auroras.

Berlin

Physiological Society, October 29.—Prof. du Bois-Reymond in the chair.—Dr. J. Munk reported on experiments instituted by him in the course of the last two years with a view of arriving at an experimental decision between the two theories of the secretion of urine: the filtration theory of Ludwig, and the secretion theory of Heidenhain. According to the first theory, the blood-pressure prescribed the measure for the urine secretion; according to the second theory, the urine got secreted from the secretory epithelial cells of the kidneys, and the quantity of the matter secreted was dependent on the rate of movement of the circulation of the blood. The speaker had instituted his experiments on excided but living kidneys, through which he conducted defibrinised blood of the same animals, under pressures which he was able to vary at pleasure between 80 mm. and 190 mm. Fifty experiments on dogs whose blood and kidneys were, during the experiment, kept at 40° C., yielded the result that the blood of starving animals induced no secretion of urine, which, on the other hand, showed itself in copious quantities where normal blood was conducted through the kidney. If to the famished blood was added one of the substances contained as ultimate products of digestion in the blood, such, for example, as urea, then did the secretion ensue. The fluid dropping from the ureter contained more urea than did the blood. That fluid was therefore no filtrate, but a secretion. An enhancement of the pressure of the blood flowing through the kidney had no influence on the quantity of the secretion passing away. An increased rate of movement on the part of the blood, on the other hand, increased in equal degree the quantity of urine. On a solution of common salt or of mere serum sanguinis being poured through the kidney, no secretion followed. All these facts, involving the exclusion of the possibility of a central influence being exercised from the heart or from the nervous system on the kidneys, were deemed by the speaker arguments proving that the urine was secreted by the renal epithelial cells. A series of diuretics was next tried, in order to establish whether they operated in the way of stimulus centrally on the heart or peripherally on the renal cells. Digitalis was a central diuretic. Common salt, on the other hand, was a peripheral diuretic. Added in the portion of 2 per cent. to the blood, it increased the quantity of urine eight- to fifteen-fold. Even in much less doses, it was a powerful diuretic. In a similar manner, if yet not so intensely, operated saltpetre and coffeïne, as also urea and pilocarpine. On the introduction, however, of the last substance into the blood, the rate of circulation was accelerated in an equal measure as was the quantity of urine increased, so that in this case the increase in the quantity of urine was, perhaps, exclusively conditioned by the greater speed in the movement of the blood. On the other hand, the quantity of secreted urine was reduced when morphine or strychnine was administered to the blood. In the case of the application of strychnine, the rate in the current of the blood was retarded in a proportion equal to the reduction in the secretion of the urine. The speaker had, finally, demonstrated the synthesis of hippuric acid and sulphate of phenol in the excided kidney as a function of its cells, by adding to the blood pouring through the kidney, in the first place, benzoic acid and glycol; in the second place, phenol and sulphate of soda. In order that these syntheses might make their appearance in the excided kidney, the presence of the blood-corpuscles was not necessary, though, indeed, the presence of oxygen in the blood was indispensable.

THURSDAY, JANUARY 6, 1887

SCIENCE AND THE JUBILEE

THE year of Jubilee has come, and on all sides we hear of proposals to make it memorable in one way or another. It is right that the completion of fifty years of such a glorious reign as that of the present Queen should be celebrated by all kinds of noble effort, and the more the future greater well-being of the Queen's subjects is considered in those efforts, the more lasting such memorials will prove. But, so far, the word Science has scarcely been mentioned either in summing up the progress of the nation during the last fifty years, or in considering how science should have its place among the memorials by which this year is to be marked out from among its fellows.

This is not encouraging; still less encouraging is it that at the beginning of such a year the progress of science in this country finds itself jeopardised in a serious manner. According to rumour part of Lord Randolph Churchill's famous "plan" was to increase his reputation not only by crippling our national defences but by paralysing all those efforts to spread science broadcast in our land for which the Science and Art Department and other kindred organisations, such as the British Museum, are responsible. To effect any large economy in this direction science schools must have been swept away, science classes crippled, science scholarships abolished, and science museums cast into the limbo of ineffectiveness.

Truly the politician's trade is a curious one; for, supposing the rumour to be well founded, and that all these things had been proposed, what then? In a week the common-sense of the country would have found out that the Government which could sanction such measures was out of touch with all true progress. But suppose, further, that they were permitted to be carried out; we should just be where we were fifty years ago in many things which by common consent lie at the root of all true national progress. It is lamentable, indeed, that even yet the Philistine is so rampant among us, and that those to whom the nation looks for good government and light and leading know so little about our actual needs.

Indeed, it must be frankly conceded that in these matters our nation is fifty years behind others. Nay, more: we must possess our souls in patience for yet another fifty years: for not till then, as things go, it is to be feared, will the average politician know the *rôle* which science plays in modern progress, and the stern necessity there is, if we are to hold our own among the nations, that scientific instruction must be enormously extended.

Turning now to another matter which is engaging much attention in connection with this memorable year, we must confess to a feeling of disappointment in connection with the proposals for an Imperial Institute which we printed last week (p. 210). The Committee who drew up the Report, on which, no doubt, action will soon be taken, have undoubtedly avoided many errors into which they would have fallen had they followed much of the advice which has so freely been tendered to them; but we think that they have missed their mark in great measure, for the reason that the Committee too much resembles the play of "Hamlet," with the Prince of Denmark omitted. It did not please the Prince of Wales to nominate any official representative of science upon it. We do not forget that the Committee had the advantage of numbering Sir Lyon Playfair among its members, but he was not there as an official representative of science, and, had he been, such representation would have been numerically insufficient. As it is, it is not difficult to surmise that many of the best suggestions contained in the scheme are his, and this makes us regret the more that he was there single-handed.

In our view, there is room for an Imperial Institute which might without difficulty be made one of the glories of the land, and which would do more for the federation of England and her colonies than almost any other machinery that it is possible to imagine. But it must be almost exclusively a scientific institution. Its watchwords should be "Knowledge and Welcome." England, through such an institution, should help her colonies in the arts of peace, as she does at present exclusively in the arts of war. In an Imperial Institute we can imagine the topography, the geology, the botany, and the various applications of science and the industries of Greater Britain going hand in hand.

This year is not only the 50th anniversary of the Queen's accession, but it is the 800th anniversary of Domesday Book. Let the Imperial Institute be the head-quarters of a bigger Domesday Book; let all knowledge be there accumulated concerning the growth of England's children during the last 800 years; let the knowledge be complete, and so arranged that what comes from each quarter shall throw light on all. Those who know how matters stand best, will see that in the case of many of our colonies this knowledge does not exist; then let it be the proud duty of the Imperial Institute to get it. We have colonies in which are large stretches of country teeming with mineral and botanical wealth where no surveyor, or botanist, or geologist has ever trod. Let the Imperial Institute bring about the arrangements by which they may be sent; we have men engaged upon all these works at home. We can imagine no greater service rendered to the science of this country than that those engaged upon its various surveys should enlarge their experience by that "travel, travel, travel" upon which Sir Charles Lyell insisted. The presence of such men for a few months in those colonies where surveys have not already been established would be of inestimable advantage on both sides; and if the system were at work for a few years it would be found that there is no more necessity for a colony, unless it prefers to do so, to establish the whole mechanism of a Geological Survey and a Topographical Survey for itself than there is for it to establish an Admiralty or a War Office.

We would by no means limit this scientific outlook to surveys merely. Take the present condition of Barbados as a case in point. Barbados must either start some new industry or she must starve. This new industry must depend upon new knowledge. We take no steps to help Barbados with our brain power, as if it was not our concern; but if Bridgetown were under the guns of a foreign fleet, the whole money and muscle power of the Empire would, if necessary, be at her disposal.

We have said enough to indicate the general direction in which we believe the Imperial Institute can do the noblest work, and can make itself felt more and more as years roll on, and we believe that if the future governing body of the Institute is a truly representative one, that is, if science is properly represented on it, by such men as the President of the Royal Society, the Directors of the Royal Gardens and of the Geological and Topographical Surveys, that such functions as those we have suggested will be obvious.

To turn now to another part of the scheme, the Report wisely suggests that the new Emigration Office should form part of it. With this we cordially agree. But the return current must be provided for. Those who have lived in England's colonies and dependencies know best the intense home feeling, and in many cases the stern necessity there is of close contact with the mother country. Let the Imperial Institute be England's official home of her returning children, the Hall in which she officially welcomes them back. Let them here find all they need, and let information and welcome be afforded with no stinted hand.

Along the two large lines we have indicated, we believe that there are efforts to be made which could only be effective as connected with such an institution as an Imperial Institute, and we believe that they are more germane to its functions than some of the minor utilities shadowed forth in the Report.

The Committee has certainly made out its case in favour of South Kensington. And it will be generally conceded that, if the Institute has for its chief objects the binding together of the various developments of science and art in the mother country and her colonies into one homogeneous whole, the Commissioners for the Exhibition of 1851 would be perfectly justified in making the valuable gift to the Institute which is referred to in the Report. We shall not follow the *Times* in gibing at South Kensington. To us South Kensington means the Science and Art Department, with its schools, museums, and laboratories, and the Natural History Museum; and we know that these institutions have had no more to do with the various shows there during the last few years than they have with the services of the Oratory, with which they are also geographically associated.

It is with several unpleasant reminiscences connected with these shows still in our minds that we are somewhat doubtful of that part of the Report which refers to the exhibitions of various Imperial products, and we believe the only safeguard possible, if they are really instituted, would be that they should be open free to the public like the National Museums.

HISTORICAL GEOLOGY

The Student's Hand-book of Historical Geology. By A. J. Jukes-Browne. (London: George Bell and Sons, 1886.)

GOOD wine needs no bush, but every prudent vintner will carefully abstain from hanging out a sign calculated in any way to convey to the passer-by the impression that the liquor to be obtained within is of inferior quality. If authors were equally cautious, we should not see, as in the case before us, a good book disfigured by a frontispiece, to say the least, not calculated to produce a favourable impression on the mind of one who opens the work for the first time. The plate in question is a fanciful representation of what some one has imagined may have been the distribution of land and sea during the Carboniferous period. It depicts the present bed of the North Atlantic as then occupied by a broad tract of continental land. Now, when we picture to ourselves a long tongue of land running out, during Carboniferous times, from Scandinavia across the Highlands of Scotland and on to the north and west of Ireland, we are well within the bounds of legitimate speculation. The arguments in favour of such an hypothesis are too well known to need reproduction here. Again, when we look at a geological map of North America, and note how the great central tract of Palæozoic formations is even now hemmed in on the north and east by a belt of Archæan rocks, we are indulging in no improbable supposition if we infer that, during Palæozoic times, the eastern Archæan strip extended further to the east than now, and that from it was derived part of the material for the formation of the rocks of the Palæozoic basin. But it is obviously quite another thing if, on the strength of these two highly probable suppositions, we proceed to fill up the whole of the intervening ocean. It is a puzzle to our mind to imagine on what grounds any one can pretend to know what was the condition of things in mid-Atlantic so far back in the earth's history, and any attempt to lay down such a map as figures in the frontispiece to the present volume seems to be about as striking an instance as can be found of the unscientific use of the imagination.

Luckily a very slight acquaintance with the book itself will dispel the unfavourable impression likely to be created by its frontispiece, but the introduction of this map has permanently impaired the usefulness of the present edition, because the money spent on it would probably have sufficed to furnish a number of illustrations of real value, which are very much wanted. The book contains careful descriptions of the physical geography of the British Islands at different geological periods, but mere verbal accounts of the distribution of land and sea are hard to follow; and if each had been accompanied by a small outline map the value of these really important descriptions would have been more than doubled.

To pass to our author's treatment of the several formations. In the case of each he begins with a general sketch, in which he explains, among other matters, the grounds on which the formation was established and received a distinctive name; then follows a summary of the life of the period, illustrated by woodcuts of rather unequal execution; after this he proceeds to detailed stratigraphy, describing the minor subdivisions and the lithological character of their rocks at the principal localities where the formation has been studied; and he concludes with restorations of the physical geography of each period. Detailed stratigraphy in a work of the present size must necessarily be very condensed; and it is a question whether under this head an attempt has not been made to be too encyclopædic. In his nomenclature the author perhaps shows some weakness for new names; the restorations of old physical geography seem to be accurate and cautious, and as successful as they can be made without illustrative maps.

In the account of the Archæan rocks he displays a caution and a freedom from dogmatism and partisan feeling which it is much to be wished were more general among the students of this nest of obscurities.

In the oldest Palæozoic rocks (we hardly dare name them, for no nomenclature can be adopted without bringing a storm about one's ears from some quarter), Prof. Lapworth's triple nomenclature is adopted. It would be a comfort if the term "Ordovician" could meet with general acceptance, for there would then be a chance of our knowing what any author meant by Cambrian and what by Silurian, without long and wearisome inquiry as to what camp the said author attached himself to. Our author's weakness for new names, we think, shows itself in the Silurian subdivisions. It is by no means obvious why our old friends "Ludlow" and "Wenlock" are to be displaced by "Clunian" and "Salopian." We had thought, too, that it was generally admitted that the old "Tilestones" and "Downton Sandstone" had no business in the Ludlow group, and that they had better be placed by themselves as "passage beds" between the Silurian and Old Red.

In his treatment of the Devonian the author displays commendable caution. He reproduces on p. 158 a fanciful attempt to correlate the minor subdivisions of the marine Devonian and lacustrine Old Red, but admits that it requires "further examination." There is also a good summary of the recent researches of Prof. A. Geikie and Prof. Hull on the Old Red of Scotland and Ireland. Here, and generally, the book is well up to date.

There are some rather serious objections to be made to the chapter on "The Carboniferous System." The Lower Coal-measures and Millstone Grit are stated to be "partly marine," the Middle and Upper Coal-measures to be "fresh-water." Now, whatever reasons there may be for calling the Lower Coal-measures and Millstone Grit marine in part, apply to the Middle Coal-measures as well. Marine shells occur in the Millstone Grit and Lower Coal-measures; but every one who has looked at the question with a critical eye takes careful note of the fact that they are the exception, not the rule, for they are found only in a few thin bands. Marine shells occur also in the Middle Coal-measures, but here again they are confined to a few thin bands. In short, throughout the bulk of the beds classed as Millstone Grit and Coal-measures, fossils unquestionably marine are strikingly conspicuous by their absence; but from bottom to top, with perhaps the exception of the very uppermost Coal-measures, we every now and then come across a thin band containing, often in great abundance, fossils that are certainly marine, and some of them Carboniferous Limestone species. The inference surely is that the Millstone Grit and Coal-measures are in the main estuarine or fresh-water, but that every now and then the sea broke in and flooded the basin in which they were formed. There are other considerations, too long to be reproduced here, which seem to lead to the same conclusion. They are summarised in "Coal, its History and Uses" (Macmillan, 1878), pp. 50-53. It is hardly fair, however, to blame our author for any shortcomings he may have been guilty of in this matter. He has evidently followed Prof. Hull, and knowing, as he doubtless does, what unrivalled opportunities Prof. Hull has had for studying the Carboniferous rocks, it was only natural that he should look upon him as a trustworthy authority. But when Prof. Hull's statements and tables come to be analysed, they break down sadly. In his general table of the British Carboniferous Series (*Quart. Journ. Geol. Soc.*, xxxiii. 615), we read: "Middle Coal-measures (fresh-water and estuarine). Marine species rare." "Ganister Beds. Essentially marine. Fossils marine." Perfectly true, but only half the truth. Marine species are rare in the Middle Coal-measures, but they are rare in the Ganister Beds also; in both equally they are absent from the bulk of the formation, and are found only in certain bands, always thin, and few in number. This latter fact, which seems to us to be of the utmost significance, is unluckily overlooked by Prof. Hull. Again, in his tabular summary of Carboniferous Mollusca, Prof. Hull has marshalled what looks like a formidable list of marine forms in the column for the Ganister Beds, while only comparatively few occur in the column headed Middle Coal-measures. But against this we have to set off the fact that the marine shells of the Ganister Beds come almost exclusively from beds such as ironstones and the roofs of coals which have been largely worked; while, with I think one exception only, the marine shells of the Middle Coal-measures are not found in beds economically valuable, and therefore largely explored. It is only an additional instance of the truth that there are two ways of looking at statistics, the one arithmetical, and the other rational, and that the purely arithmetical aspect is always full of risk.

Two very interesting borings into the Permian, or, as our author prefers to call them, Dyassic, beds are quoted on p. 239. But it is hardly right to say that the Middlesbrough boring shows beds "not found anywhere along the outcrop." The "Magnesian Limestone, 52 feet, and Grey Limestone, 15 feet," may well be the "Brotherton Limestone" of the Yorkshire section on the opposite page; and the "gypsum, rock-salt, and marl" beneath fit in exactly with the "Middle Marls" of Yorkshire. In the Scarle bore-hole the great thickness near the base of the Permian of beds largely sedimentary ("shales and dolomites, 193 feet") indicates that we are here approaching the eastern shore of the lake in which the Permians of the north-east of England were accumulated. It seems to us that perhaps rather too much stress is laid on the unconformity between the Permian and Carboniferous. It is marked enough, of course, in the north-east of England, but elsewhere, as in North Staffordshire and Denbighshire, it does not seem to be an easy thing to say exactly where the Coal-measures end and the Permian begins. Now it is, to say the least, worth notice that, in those localities where the unconformity is strong, the Upper Coal-measures are absent or only feebly represented; but that where we find Upper Coal-measures in force, the unconformity is less strongly marked, and perhaps in some places there may be no unconformity at all. Can this be the explanation? In some places, the north-east of England for instance, the absence of the Upper Coal-measures is not due to denudation; there never were any Upper Coal-measures there. What may be called the Upper Coal-measure period was in these localities not a period of deposition, but of upheaval and denudation among the Carboniferous rocks; and so, when, later on, the formation of Permian rocks began, these rested on upturned and largely denuded Carboniferous beds. Elsewhere, as on the west side of England, there was no break of this kind, but sedimentation went on continuously, or with but very slight interruption, from Carboniferous into Permian times, and there is what practically amounts to a passage from Carboniferous into Permian rocks.

There is one very healthy sentence in the chapter on "The Dyas." "There is no proof that the red rocks" (of the English Permians) "are as a whole older than the limestones, and the notion of their being so is a mere assumption founded on their lithological similarity to the German Rothliegende." If the author had said "fancied similarity," it would have been still more to the point; but it will be most useful to have clearly stated that this correlation, so dear to the pigeon-hole systematists, has nothing to rest upon.

Before concluding, we would call attention to three omissions which it seems desirable to notice. In the account of the Lower Oolites of the Yorkshire coast there is no mention of the marine band discovered by the Geological Survey and named the Ella Beck Bed (*Memoirs* of the Geological Survey, explanation of Quarter Sheet 95, N.W., p. 33). This is a very small matter; but we think it is very much to be regretted that no word has been said, in the account of the Cretaceous rocks, of the southern type of that formation, the Hippurite Limestone, and that in the description of the Tertiary rocks the Nummulitic formation is also passed by in silence. The book is primarily a book on British geology, but in cases, like that of the Triassic rocks, where the British representatives are abnormal or exceptional, the author has not hesitated to take his readers to foreign localities where the normal type is found. Now surely the rocks of the Anglo-Parisian Cretaceous basin are decidedly exceptional in their character, and were formed to a large extent under very special conditions; and the best way to enforce this truth on the reader is to introduce him to the beds of the same age deposited elsewhere in a less special manner. The large range too of the Hippurite Limestone gives it precedence over the deposits laid down in what was after all only a biggish and somewhat land-locked inlet of a western ocean. And the same thing may be said, even with more emphasis, of the Eocene beds. What an imperfect idea any one would have of the physical geography and events of that period who knew only the littoral and estuarine representatives found in the London and Paris basins. If space were an object, it would have been better to have omitted many things which now find a place in the book than to have passed over two such formations as the Hippurite and Nummulitic Limestones. For instance, it seems to be a fixed article of faith that every geological text-book must contain an account of the Permians of the Thüringerwald, a little isolated group with a very special character of their own, and with little or no bearing on British geology, but, as has been said, dear to the pigeon-holers. The omission of the account of this group, and of one or two similar sections of the book besides, would have left ample room for all that need have been said about the two great formations mentioned above.

Such little flaws as have been noted seem to be present in the structure of what, on the whole, will prove a most useful book. If any of the suggestions we have made commend themselves to the author's judgment, we trust he will soon have an opportunity of acting upon them in a second edition.

A. H. GREEN

PHOTOGRAPHS AND DESCRIPTIONS OF WILD ANIMALS

Wild Animals, Photographed and Described. Illustrated by Phototype Reproductions of Photographic Negatives taken from Life. By J. Fortuné Nott, Major, Canadian Active Militia. (London: Sampson Low and Co., 1886.)

THE author of this splendidly printed volume, while disclaiming the idea that it is an erudite or scientific work on natural history, assures us that his object in writing and compiling it was to furnish some trustworthy information about some few of the most important varieties of existing wild animals, and to do this in an entertaining and readable manner. The works at present in existence on such a subject may be classified, the author thinks, into the "scientific" and the "educational": the former are, in great measure, incomprehensible to the general reader; the latter have their value to the same class of reader greatly spoiled by the taint of levity that characterises the style in which they are written. When a bear is talked of as "Master Bruin," and a lion as "His Majesty," the dignity of the subject is compromised.

This being so, Mr. Nott thought there was room for a book which "would accurately describe the salient features, distinguishing peculiarities, and specific habits" of wild animals, and that by dropping, as far as possible, all scientific descriptions and the general use of scientific nomenclature, and adding certain historical facts or interesting anecdotes in which they prominently figured, he could make such a volume readable and entertaining.

It is, however, obviously impossible that any one man could personally be familiar with the habits of all of our larger animals, and the author has borrowed a good deal from the works of travellers that "have appeared within the last few years, rather than from similar works of previous dates, wherein fable and truth are so blended that they were practically useless" for his purpose.

Respecting the illustrations of this volume, the author has attempted a new departure. Instead of illustrating his book with portraits of animals taken by artists, which often represent rather the artists' ideas of what an animal ought to be than what the animal really is, he has had photographs of these wild beasts made, and illustrates the volume with phototype reproductions of these. He apologises for the photographs, owing to the difficulties encountered. It is difficult to get human beings to sit properly for their portraits, but wild animals must be taken often in darkish dens, and are not amenable to orders to keep quiet and look their best.

To our mind, these photographic illustrations are the more important portion of this volume, which, from its fine type and paper, and wealth of illustration, is likely to become popular. The photograph of the lion is excellent. This beast, as our author would call him, has behaved extremely well under the trying ordeal, and has "come out" first-rate. The group of zebras form a pretty picture. The photographs of the giraffe, hippopotamus, and red kangaroos are characteristic. The text calls for little comment: we have descriptions of a large number of familiar wild animals, and in these the author has undoubtedly avoided as much as possible being at all scientifically exact. In our opinion the work would have gained in value and interest, and as an "educational" work, if the author had taken care, when he had to use scientific phrases, that he did so with some meaning. Thus it appears odd, to say the least, to read: "The bears, genus Ursidæ, belong in natural history to the sub-order Carnivora"; and that the kangaroos belong to the genus Macropodidæ. It would not have required a large knowledge of logic or science to avoid such mistakes.

Most of the photographs are from animals in the London Zoological Gardens, which will give a special interest to the volume.

OUR BOOK SHELF

First Year of Scientific Knowledge. By Paul Bert. (London: Relfe Brothers, 1886.)

THIS is an English edition of a little book which made M. Paul Bert's name familiar to a vast number of persons in France who knew nothing of his eminence either in science or in politics. As the title indicates, it is intended for children beginning to study science, and we know of no book better adapted for this purpose. It is a book of great merit both in style and selection of subjects. The more experimental sciences are treated as their nature demands—practically; the experiments are simple, and few will find any difficulty in performing them.

The illustrations constitute one of the special features of the book, for a diagram often conveys more meaning than a whole page of print. The language throughout is clear, and everything is simply yet accurately explained. As an example we may refer to p. 333, where the popular fallacy respecting the so-called "respiration of plants" is disposed of:—

. . . "Thus, simultaneously, in the same plant, two opposite phenomena take place: the production of carbonic acid by the parts that are not green, and consumption of carbonic acid by those that are green. Only, the latter activity being much more powerful than the former, the plant not only does not augment the proportion of carbonic acid in the air, but consumes what it finds there. . . . The decomposition of the carbonic acid by the green parts is quite the reverse of respiration, and bears a much closer resemblance to digestion."

The general character of the book leaves little to be desired.

La France en Indo-Chine. Par A. Bouinais et A. Paulus. (Paris: Challamel Ainé, 1886.)

THE important events of the last few years in Annam, Tonquin, and Cambodia have given rise to a quantity of literature in France, relating to this region, which has now reached enormous proportions. French periodicals of all kinds are full of papers relating to it, and new books on the same subject have been issued in many scores during the past three years. Every department of research is represented—historical, scientific, literary, antiquarian, industrial, commercial, &c. If this great flood represents, as it undoubtedly does, the keen interest taken by the French people in the countries with which they have now so close a connection, it is none the less embarrassing to foreign readers who desire to obtain a general and accurate survey of Indo-China. Amid the host of works, good, bad, and indifferent, now issuing from the French press on this region, and on every conceivable topic connected with it, it is difficult to select one which contains all that is wanted by the ordinary cultivated person, who desires to have some knowledge of countries which have been the theatre of events that have moved Europe profoundly. At last MM. Bouinais and Paulus have produced such a book. Capt. Bouinais has served long in Tonquin, and is actually a member of the Frontier Delimitation Commission, and Prof. Paulus, of L'Ecole Turgot, though, we believe, he has never visited the country, has made it a special study, and has laboured to popularise a knowledge of it in France. The two authors have already published a very much larger work on the same subject, of which the present one appears to be an abridgment intended for wider circulation and more general information.

Perhaps the most satisfactory manner of reviewing a work such as this, which covers a large and varied field with brevity, is to describe shortly its arrangement and contents. The first chapter refers to the geography, orography, hydrography, and climate of Indo-China, including in this term French Cochin China, Cambodia, Annam, and Tonquin. The second chapter deals with the history of French intercourse with these regions, commencing, properly speaking, with the cession to France of Tourane Bay and Pulo Condor in 1787, a cession which was due to the management of Pigneau de Béhaine, Bishop of Adran *in partibus*. All the interesting and exciting incidents of the occupation of Saigon, the Garnier and Philastre missions to Tonquin, and the events succeeding the death of Rivière down to the death of Courbet and the peace with China, are recounted with perfect clearness and accuracy. Next, the inhabitants are described, as well as the towns, and forms of religion prevailing in the countries. The aboriginal population is treated under the heads Moïs, Chams, and Muongs, a division which is perhaps sufficient in a book intended for popular reading, but which the authors themselves acknowledge to be wholly inadequate, as they refer also to "savages inhabiting the mountains," the phrase usually employed by the Chinese when speaking of a people about whom they know nothing. The ethnological questions connected with the Moïs, Muongs, Chams, and the unnamed "savages" can scarcely be answered for many years to come; but they are amongst the most interesting ones connected with ethnology in the Far East. The origin and relationship of these and other scattered fragments of once powerful peoples, not in Indo-China alone, but in Upper Burmah, and all over China south of the Yangtsze, did not come within the scope of MM. Bouinais and Paulus's work, although the latter shows how little is known about them when they are all classed indiscriminately as "savages of the mountains." The fourth chapter deals with productions, trade, and communications, and the fifth with the administration in each of the countries mentioned. Finally comes a chapter on the future, a political forecast, to which we need not refer further. The work, it will be seen, goes over the whole field, and, as far as we have been able to check the statements, it is very accurate. As there is no English book on the subject, this may be recommended to readers who desire to know something of the new region which is but now being brought into close contact with Europe. Whether the French are a colonising or only a conquering people, though much debated, is a question with which we are not concerned here: what is beyond all question is that no effort is spared by the Government or the public to acquire that first indispensable requisite of all good and intelligent government, viz. a knowledge of the country and people to be governed. No expense is considered too great, no labour too burdensome, to obtain this knowledge. In this respect they set an example which one more successful colonising nation at least might well follow.

My African Home. By Eliza Whigham Feilden. (London: Sampson Low, 1887.)

IN 1852 Mrs. Feilden and her husband went to Natal, where they remained for five years. On her return to

England her letters were restored to her, and in the present volume she has arranged them in chronological order, with extracts from her journal. The book contains a mass of petty details in which few readers will find much to interest them; but there are also some very good sketches of the scenery of Natal and of the rough, free-and-easy life of the colonists. Mrs. Feilden was much impressed by the fertility of the soil, and by the beauty of the vegetation with which she was surrounded. "As for fruits, vegetables, and flowers," she wrote, "you have only to put the seeds and young plants in the ground and they grow. There is no end of season in Natal." She remarked that there were not many native fruits, but that all that were imported seemed to suit the soil and climate. The native flowers she considered "very exquisite." They "grew in great variety and luxuriance, with the waxy look of hot-house plants." As for birds and insects, the air teemed with them. Of the Caffres Mrs. Feilden formed a very poor opinion. "The Caffre is indolent; he lives only like the beast, to eat and sleep, and pass through life with ease; but to do this he must have his land tilled, and to purchase wives to till his land he must have cows to pay for them. He sells his daughters to be drudges to other Caffres, while the boys and young men go out to work for the white man, till they can in turn buy cows and wives." Even Caffres, however, have one good quality: "they heartily share anything they have with each other, and eat out of the same pot without the least feeling of who shall have most." To Mrs. Feilden they seemed to be rather like Jews, and she asks whether they may not be descendants of Ishmael or an offshoot from the lost tribes—from which it may be inferred that in the list of subjects she has tried to study ethnology has not yet been included.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Coal-Dust Theory

UNDER the title of "A New Mining Danger," the *Yorkshire Post* of the 16th ult. published its final report on the proceedings at the inquest on the bodies of twenty-two men and boys who perished in an explosion at Altofts Colliery, Normanton, on the 2nd of October last.

The inquest was commenced immediately after the explosion, but was adjourned until the workings could be sufficiently re-opened to admit of a careful examination being made into all the circumstances. It was resumed and concluded on the 13th, 14th, and 15th of December. The witnesses, including Mr. F. N. Wardell, Her Majesty's Inspector of Mines for the district, were unanimously of opinion that the explosion was originated by the firing of a shot in the stone or rock constituting the side of one of the main thoroughfares of the colliery, which was also a main intake airway; and they were of opinion that it had expended part of its energy in raising and igniting a cloud of coal-dust, which formed the nucleus whence the explosion was propagated.

The coroner in summing up agreed with this conclusion, and the jury returned the following verdict:—

"That the whole of the workmen killed, except Deakin and Lomax, met their deaths from an explosion of coal-dust, which originated in the west chain road, which explosion was caused by the firing of an unskilfully drilled shot by one of the men engaged in widening the road; and that Deakin and Lomax were suffocated by the stoppage of ventilation consequent on the explosion."

The coal-dust theory, which is discussed at some length in the Final Report of the Royal Commissioners on Accidents in Mines, postulates that coal-dust may not only serve to originate an explosion, under certain given conditions, but may continue to carry it on as far as the same conditions extend. The essential conditions appear to be: that the coal-dust be perfectly dry, in a very fine state of division, and fairly abundant in quantity; that the initial cause be a large flame expanding with sufficient force to propel the air rapidly in front of it, so as to raise a cloud of coal-dust; and, lastly, that the explosion take place in a confined space, such as the workings of a mine.

From the first this theory was intended to account for great explosions in mines, or accomplished facts, which seemed to be otherwise inexplicable. It has nothing to do with mines in which explosions have not taken place, except to point out a possible source of danger; and arguments opposed to it which are based upon the fact that all kinds of coal-dust are not equally inflammable are therefore obviously inapplicable. It was adopted by the Prussian Commissioners as being applicable to certain inflammable dusts in a minute state of subdivision, but not to others of a somewhat different chemical composition. In discussing the Camphausen explosion in NATURE (vol. xxxi. p. 13), I pointed out that the conclusions arrived at from a consideration of the experimental results obtained with Camphausen dust by the Prussian Commissioners, fell far short of the actual occurrence in the colliery, and that the same relation would probably obtain in the case of all the other dusts experimented with, provided all were made equally fine.

MM. Mallard and Le Chatelier, whose conclusions were accepted by the French Commission, of which they were members, rejected the coal-dust theory, and endeavoured to reason away all apparently confirmatory arguments drawn from the consideration of actual explosions in mines.

In this country it has been accepted by some of the Inspectors of Mines, and more particularly by Messrs. W. N. and J. B. Atkinson, who uphold it vigorously in their treatise on "Explosions in Mines," which was recently reviewed in NATURE (Nov. 4, 1886, p. 1) by Prof. Thorpe. It appears also to have found favour with a number of mining-engineers and colliery managers, both here and abroad. There seems, however, to be some doubt as to how far it was accepted by the Royal Commissioners on Accidents in Mines, and I shall therefore quote their own words on the subject:—

"In emphasising this claim (Proc. Roy. Soc., vol. xxxvii. p. 43), Mr. Galloway does not appear to have realised the fact that, *if dust were the principal agent* in coal-mine explosions, *every* blown-out shot occurring in a *very* dusty and dry mine should actually be attended by a more or less disastrous explosion or conflagration, and that, looking therefore to the enormous amount of powder expended in shot-firing in this and other countries, and to the not inconsiderable proportion which blown-out shots must constitute, in many localities, of the total number of shots fired, disastrous coal-mine explosions should be of more than daily occurrence, if his view were correct."

I submit that the conclusion here stated is not deducible from the premiss; and in support of this position I adduce the fact that coal-dust is *admitted* to have been *the principal agent* in two of the most disastrous explosions of the present year, namely, those of Mardy and Altofts collieries, in both of which shots were fired. Altofts Colliery alone is sufficient to prove the case against the Commissioners, for it has been in operation for twenty-one years, and shot-firing has been carried on in it during the whole of that period. If, then, blown-out shots constitute a "not inconsiderable proportion" of the whole, there is a probability amounting to a certainty that such shots must have been fired in Altofts Colliery many times without the results here postulated having been attained until now. The argument as made use of against my own views appears therefore not to be in accordance with ascertained facts.

It may be safely maintained, therefore, that every blown-out shot does not fulfil the whole of the conditions necessary for creating an explosion. For instance, the dust may not be present in sufficient abundance within reach of the flame; it may not be fine enough to ignite at the point where the shot explodes; it may contain too much foreign matter, or be covered with coarse rubbish, or be locally damp; the shot may be too high, or too low, or pointed in an unfavourable direction; the direction and velocity of the passing air-current may exercise some influence on the result; the creation of a nucleus of explosion may in certain cases be facilitated by the previous formation of a cloud of coal-dust to windward, raised by another shot (as imagined by the late Prof. Marreco and Mr. D. P. Morrison), or by a fall of roof, a train of mine waggons that has just passed, or any other accidental circumstance, and subsequently carried past the mouth of the shot-hole at the instant the flame issues from it."

Immediately after the passage quoted above the Commissioners proceed to say :—

"The following facts relating to the part played by dust in coal-mine explosions may, however, now be regarded as conclusively established :—

"1. The occurrence of a blown-out shot in working-places *where very highly inflammable coal-dust exists in great abundance*, may, even in the total absence of fire-damp, possibly give rise to violent explosions, or may at any rate be followed by the propagation of flame through very considerable areas, and even by the communication of flame to distant parts of the workings where explosive gas-mixtures, or dust-deposits in association with non-explosive gas-mixtures, exist."

"2. The occurrence of a blown-out shot in localities *where only small proportions of fire-damp* exist in the air *in the presence of even comparatively slightly inflammable or actually non-inflammable, but very fine, dry, and porous dusts* may give rise to explosions the flame from which may reach to distant localities, where either gas accumulations or deposits of inflammable coal-dust may be inflamed, and may extend the disastrous results to other regions."

This has the appearance of conceding all that is asked, but when read in the light of the first quotation it leaves the matter in considerable doubt. Indeed, it was stated at the inquest on Altofts explosion that the proprietors of that colliery had not gathered from the Commissioners' Report that they were running any risk of an explosion, such as the one that happened ; and at the inquest on Elemore explosion, which has been adjourned until the 18th inst., Mr. Lishman, the manager, gave utterance to similar sentiments. Be this as it may, it is obvious that legislative measures ought to be adopted without further delay, with the object of rendering the recurrence of coal-dust explosions impossible for the future. In providing against them it must also be recollected that a local explosion of fire-damp, such as the one which originated Mardy explosion, produces exactly the same result as a blown-out shot fired under the most favourable conditions imaginable.

Cardiff, January 5 W. GALLOWAY

The Cambridge Cholera Fungus

IN your issue of December 23 (p. 171) appears a letter from Dr. E. Klein, in which that gentleman attempts to show that the micro-organisms found by Dr. Graham Brown, Mr. Sherrington, and myself in the substance of the mucous membrane of the small intestine in cases of *Cholera asiatica* are nothing more than "common mould (probably aspergillus)," which has grown on and into the tissue during the process of hardening. We were and are, however, perfectly well acquainted with the fact that imperfectly preserved animal tissues are liable to be invaded by various forms of fungi, and took, therefore, precautions which we believe to be ample to prevent such contamination of our material. Moreover, the presence of the micro-organisms in certain parts of the tissues only, their absence in others or on the surface of the specimens, the fact that their presence in the part is accompanied by anatomical changes which could not have taken place during the process of hardening, and, most of all, the characters of the micro-organisms themselves, render such an hypothesis as that brought forward by Dr. Klein absolutely unacceptable.

It is unnecessary for me to answer all the arguments advanced by Dr. Klein in support of his views on this subject. They prove nothing more than that fungi grow on and in animal tissues which are not adequately preserved—a fact which no one will doubt. That, on the other hand, the micro-organisms found by us are of this nature is a matter which neither Dr. Klein nor any other person who is unacquainted with the facts is in a position to decide. Since a short preliminary account only of the work done by Dr. Graham Brown, Mr. Sherrington, and myself, on the pathology of cholera has as yet been published, Dr. Klein has not before him the facts on which alone a decision of any value is possible. An Error in Maxwell's "Electricity and Magnetism"

THE criticism of Mr. McConnel upon Maxwell's derivation of the inductive action of currents from the principle of energy is perfectly correct. It is inconsistent with the experimental facts appealed to by Mr. McConnel and Mr. Maxwell's own treatment of the field as the seat of electro-kinetic energy.

In the excellent treatise of Messrs. Mascart and Joubert, a similar misleading appeal is made to Helmholtz's proof, and I have little doubt that Maxwell has correctly stated it. I should be inclined to think that the existence of the energy of the field was not distinctly present to Helmholtz's mind.

Maxwell, as is well known, by an ingenious application of Lagrange's equations of motion, proves that, in the case of two currents, this electro-kinetic energy T_e is given by the equation—

$$T_e = \tfrac{1}{2}(L_1 i_1^2 + M i_1 i_2 + L_2 i_2^2),$$

where $M = \int\int \frac{\cos \epsilon}{r} ds ds'$ taken round both circuits, and L_1 and L_2 are similar expressions for the separate circuits.

I believe, though I dare not trespass upon your space to give the reasoning *in extenso*, that this result may be obtained somewhat more simply and without the use of the Lagrangean equations, a treatment which has the disadvantage of assuming the electric co-ordinates y_1 and y_2, the currents being $\dot{y}_1$ and $\dot{y}_2$. Then the equation of energy becomes

$$A_1 i_1 + A_2 i_2 = \frac{dT_e}{dt} + \frac{dT_m}{dt} + R_1 i_1^2 + R_2 i_2^2,$$

where T_m is material kinetic energy, and $\frac{dT_m}{dt} = i_1 i_2 \frac{dM}{dt}$ supposing the circuits rigid. Therefore

$$A_1 i_1 + A_2 i_2$$
$$= i_1 \left\{ \frac{d}{dt}(L_1 i_1 + M i_2) + R_1 i_1 \right\} + i_2 \left\{ \frac{d}{dt}(L_2 i_2 + M i_1) + R_2 i_2 \right\},$$

reducing to Mr. McConnel's equation, when the currents are constant.

In the case of two circuits thus moving in connection with their batteries we may infer that A_1 and A_2 must be such functions of i_1 and i_2, and the coefficients of configuration, that, when the suffixes are interchanged in the expression for A_1, that for A_2 must result, and *vice versâ*. If this be so, then the aforesaid equation necessitates the separate equations—

$$A_1 = \frac{d}{dt}(L_1 i_1 + M i_2) + R_1 i_1 \ ;$$

$$A_2 = \frac{d}{dt}(L_2 i_2 + M i_1) + R_2 i_2.$$

Or Maxwell's equations are obtained without the use of Lagrange. HENRY W. WATSON

The Manipulation of Glass containing Lead

IN a note on this subject in NATURE (Dec. 16, p. 150), Mr. H. G. Madan has made a suggestion which is likely to be very valuable to those who require to manipulate "combustion-tubing" before the blow-pipe. But, in proposing the employment of oxygen in place of air to produce flames for heating glass containing lead, Mr. Madan introduces a refinement which is unnecessary ; for lead-glass may be quite as easily manipulated in flames produced by plain air and gas as soda-glass itself. The pointed flame should be employed for small objects, and the oxidising brush-flame in the case of larger objects. By the oxidising brush-flame, however, I do not mean the brush-flame as ordinarily employed, but one to which the air is supplied liberally through an air-tube without any contraction at its end, and at a steady pressure from a good blower ; care being taken, on the other hand, not to introduce such an excess of air as to reduce the temperature of the flame.

In his note, Mr. Madan quotes me as saying, in the "Methods of Glass-blowing," that the reduction of lead-glass may be prevented or remedied by holding the glass a little in front of the visible flame, with the comment that there is hardly enough heat in that region to do all that is required in the manipulation of the glass. I hope he will excuse me if I point out that in this he hardly does me justice; for, although words in the above sense are to be found on p. 18, they occur only towards the end of the preliminary treatment of the subject, attention is at once called to the objections to the method, and they are followed by a full account (with references to diagrams) of the method of adjusting the supplies of air and gas so as to produce flames *within which* lead-glass may be sufficiently heated without reduction.

I have ventured to trespass on your space to this extent, because, for various reasons, I have come to the conclusion that lead-glass is distinctly the best glass for beginners to work with, and therefore I am anxious to correct the widespread and mistaken idea that its manipulation is very difficult, and requires special appliances. W. A. SHENSTONE

Clifton, December 28

Pyrometers and Fusion-Points

I READ with much interest the letter from Naples of Dr. H. J. Johnston-Lavis, and beg to offer a few suggestions in answer to his inquiries. I have done much work with pyrometers, and for my purposes have used Siemens's water pyrometer with satisfaction.

It occurs to me, however, that the pyrometer most suitable for the volcanic lava investigations proposed by Dr. Johnston-Lavis would be either Siemens's electrical pyrometer, or the one recently introduced by Messrs. Murries and Co., 45, West Nile Street, Glasgow. It would seem that, with the latter, observations can be readily taken at a considerable distance from the pyrometer, so that the pyrometer stem might possibly be lowered into the crater, and readings of the internal temperatures taken at various depths, and possibly of the contained lava also.

With regard to the fusing points of various substances, reference may be made to the recent careful researches on this subject of Dr. Thomas Carnelley and Prof. W. C. Williams.

Wortley Iron Works, near Sheffield, January 4, 1887.

Electricity and Clocks

THE exact combination about which Mr. Wilson inquires is already in existence: it can be seen at 2, Garfield Buildings, Gray's Inn Road, in the Jensen electric bell factory. The arrangement used by Mr. Jensen—and it seems to me preferable to that suggested by Mr. Gardner—is to cause the hammer of the small clock to make electric contact in the circuit of the distant large bell as it rises in preparation for striking the blow upon its own small bell. With a rubbing contact the action is perfectly certain. SILVANUS P. THOMPSON

City and Guilds Technical College, Finsbury

Barnard's Comet

ON December 25, about 6h., with a binocular field-glass, power about 4, I noticed a third tail to this comet between the other two. It was extremely faint, but 6° long, reaching to 11 Aquilæ. The principal tail was reduced to 10° in length, and was far more conspicuous than this shorter, though much broader, tail. The shortest tail, though actually much brighter than this latter, was very indistinct with these field-glasses, being best seen with the telescope, power 20, whereas the middle tail was not distinctly visible therewith, although it showed an evident dark space immediately preceding the principal tail. With the naked eye I could see the long tail only. The head was about as bright as δ Aquilæ. T. W. BACKHOUSE

Sunderland, December 29, 1886

Meteor

I HAVE just seen a very beautiful meteor about the size of Sirius. The local time was within a minute or two of half-past 10. It started out between Pollux and the star-cluster in Cancer, and fell rather slowly in the direction of Regulus, going out before it reached that star. It had a trail, which vanished with it. The sky had just cleared after a thunderstorm.

Sidmouth, December 28 J. M. H.

Red Sunsets and New Zealand Eruptions

NEW ZEALAND eruptions have not the projectile force to cause red sunsets. Singularly, the very same current of ideas expressed by Prof. Newcomb in NATURE, vol. xxxiv. p. 340, occurred to the writer, when in Australian waters the June previous, on the deck of the P. and O. steamer *Ballaarat*, off the Great Bight, on noticing a peculiarly red northerly sunset. The newspapers at King George's Sound were full of accounts of the magnitude of the eruption of Tarawera, and it must be the fine dust from New Zealand that has passed overhead.

The atmosphere of Australia, it may be mentioned, is one of the clearest, "exceptionally free," as Prof. Newcomb puts it, "from vapours or other attenuated matter," and in which volcanic dust would tell immediately.

This suggestion disappeared at once on getting to the actual site of the New Zealand eruption, only six weeks after it had occurred, and on seeing the limited area covered with mud—a mere nothing compared with the vast stretch of country in the North Island passed through. As there was not a trace of its effects till within eight miles of the foot of Tarawera, it was simply ridiculous to suppose that any of the dust had invaded the higher atmosphere.

Besides this, the boundary of the cloud of atmospheric disturbance was distinctly seen, and the altitude placed by none of the spectators to be above 12,000 feet.

The explosion at Tarawera appears to have been merely one of superheated steam. It was different in the case of Krakatão, where the initial force had much more of the character of an explosion of nitroglycerine than of high-pressure steam, as the matter was stated to have been projected at least 40,000 feet into the air.

The magnitude of the New Zealand eruption could only be felt after getting well within the diameter of sixteen miles on which the mud fell, plastering hill and dale, evenly, of a dull gray, eighteen inches thick. Exterior to this it possessed none, and the distant results evidently were infinitesimal.

The writer also saw the "green sun" from the south of India, where it lasted for days, and has no doubt that this phenomenon was due to the dust from Krakatão, such an appearance having never been even faintly approached, before or since, from ordinary natural causes, and more impressive, because unaccounted for, than a total eclipse of the sun.

India, November 26, 1886 A. T. FRASER

THEODOR VON OPPOLZER

THEODOR VON OPPOLZER, one of the most eminent of modern astronomers, died at Vienna on December 26, 1886. He was the only son of Johannes von Oppolzer, the famous pathologist of Vienna, and was born on October 26, 1841. In accordance with the wish of his father, he studied medicine, and took his doctor's degree in 1863. From early youth he had shown great interest in astronomy, and, soon after taking his degree, he caused an observatory to be built at his own expense, and resolved to devote himself wholly to his favourite science. In 1866 he began to lecture at the University of Vienna, on theoretical astronomy, and he was soon promoted to the position of full Professor in his department. In 1870 he was asked by his Government to take charge of the operations for determining the length of a degree in Austria, and to this task he applied himself with so much energy that all the necessary observations were by and by completed, although his results have not yet been published.

Oppolzer distinguished himself in all departments of astronomical science. One of the most important of his writings was his "Lehrbuch zur Bahnbestimmung der Kometen und Planeten," a work which has already become classical. He had hoped to place the theory of the moon on a new basis, but his labours in connection with this subject were not finished at the time of his death. On his death-bed he corrected the last proof-sheets of his "Canon der Finsternisse," in which he calculates all the eclipses of the sun and moon which have taken place, or which have yet to take place, between the years B.C. 1500 and A.D. 2000.

His services to science were recognised by all the great learned Societies, and he was a Foreign Member of the Royal Astronomical Society of London. He was a man of a singularly noble personal character, and his death is deeply regretted by a wide circle of friends.

THE COLONIAL AND INDIAN EXHIBITION

CANADA.—This section of the Exhibition will be remembered chiefly for its agricultural machinery in motion, its fur, and agricultural trophies, and its large collection of furniture. The collection of fruits in the agricultural trophy has probably never before been equalled either in number, variety, or perfection of preservation, the colours of the several fruits being extremely well preserved in various solutions, such as dilute sulphurous acid for the lighter coloured fruits or salicylic acid for the darker ones. Besides these, however, there were numerous exhibits which, though less imposing to the general visitor, were of considerable interest, such, for instance, as the collection of timbers, and manufactures therefrom, photographs of American timber-trees, &c. The enormous sizes of many of the American Coniferæ were well illustrated by magnificent planks of such woods as the Douglas fir (*Pseudotsuga Douglasii*), some sixteen feet high and about ten feet in diameter, large slabs of hemlock spruce (*Tsuga canadensis*), also enormous logs of black walnut (*Juglans nigra*), and many others. Perhaps the most compact and interesting collection of timbers, however, was that from New Brunswick, where the woods were arranged so as to form a kind of design, the lower or basal portion being formed of trunks of trees, with their barks remaining, about three feet high, over this were arranged sections of the wood in frames composed of the young branches with the bark on; and above these, again, panels of the same wood as shown below, cut longitudinally and with a cross section at the base, both polished to show the grain or figure, and on the panel of each wood was painted a very good representation of a spray or branch of the plant itself. Each specimen was properly named, so that the whole thing was very complete. The series of photographs before alluded to are correct representations of the tree flora, each photograph being framed with the wood of the tree illustrated. The general use of the bark and wood of the cedar of British Columbia (*Thuja gigantea*), for useful and ornamental articles, was well shown in the exhibits of mats, native head-dresses, masks cut from the solid wood and grotesquely painted, spoons, whistles.

Fiji.—Though the space occupied by these islands was but small, the exhibits were of an interesting character, including a fine set of native timbers, for the most part scientifically named, and including some large blocks of Fijian sandalwood (*Santalum yasi*), roots of the kava (*Piper methysticum*), which is generally used in the Society and South Sea Islands in the preparation of an intoxicating beverage by chewing the root, ejecting the saliva into large bowls, and then fermenting it; or by pounding the root between two stones, then putting it into a bowl, pouring water upon it, kneading it, and afterwards straining it. The taste is said to be like that of soap-suds, but a liking for it is easily acquired, and it is said to quench the thirst better than any other beverage. A spirit prepared from it in Germany was sold in the Exhibition under the name of yagona or kava schnaps. This spirit, which is something of the nature of a liqueur, is described as having medicinal properties, and is recommended for its remarkable soothing and stimulant effects, restoring faded energies and exhausted nerve-power. Cocoa-nut fibre and oil of course form large staples of produce in Fiji, and were fully represented in the Exhibition, as well as dilo nuts and oil (*Calophyllum inophyllum*). Some excellent samples of sugar, grown and manufactured in the islands, and tea, also grown and prepared in Fiji, as well as many other products, were shown in quantity. Great credit is due to the Executive Commissioner, the Hon. J. E. Mason, for making the resources of his colony known by the distribution of small samples, during the period the Exhibition was open, to any one having a real interest in their development.

Victoria.—Besides the splendid collection of water-colour drawings of Australian plants exhibited on the north side of the Court, the fine series of Victorian woods, the golden arch, and the native encampments, all of which attracted a considerable amount of attention, the products of the genus *Eucalyptus* in the shape of oils and resins, exhibited by Mr. Joseph Bosisto, M.P., and President of the Commission, were amongst the most interesting and important. Samples of the oil of *Eucalyptus amygdalina*, rectified and non-rectified, were shown. This is the best quality of eucalyptus oil, and the oil for the preparation of which Mr. Bosisto's firm has become noted. A sample of the essential oil of eucalyptus of commerce was also shown, and described as being obtained from the allied varieties of *E. amygdalina*, but not from the true species. So many varieties of this species are known that it is difficult for bushmen who collect the leaves to distinguish those of the true species from its congeners, forming, as they often do, a compact jungle or bush growing in close proximity to each other. The oil is rubefacient, antiseptic, disinfectant, and a deodorant of great power. The essential oil of *Eucalyptus globulus*, the blue gum-tree of Victoria, having tonic, stimulant, and antiseptic properties, as well as those of *E. oleosa*, *E. dumosa*, *E. citriodora*, *E. goniocalyx*, *E. obliqua*, &c., were also shown. A sample of eucalyptol from *E. amygdalina* and *E. globulus* is described in the Catalogue as "a homologue of camphor, and appears to be two steps higher in the series. Its vapour, mixed with air, is agreeable when inhaled, and is employed as a therapeutic agent in bronchial and diphtheritic affections." Amongst resins were those of the red gum of Victoria (*E. rostrata*), described as a thoroughly soluble and delicate mucilaginous astringent, and *E. resinifera*, Australian kino. Fine samples of the resin of the Australian grass-tree (*Xanthorrhœa hastilis*) were also shown. This is obtainable in large quantities; it is of a deep amber colour, soluble in spirit, and is used for staining wood to imitate cedar and oak, and is also used in this country in French polish to deepen the colour of light mahogany and other woods.

New South Wales.—Minerals, wools, timber, and furniture made of the timber, were the principal objects exhibited. None of the woods called for any special remark except, perhaps, a small collection either known or considered to be adapted for wood-engraving, and these specimens were of little or no value in themselves, being badly selected, and in many cases much split or cracked. The collection was more valuable as giving a clue to the source of the woods considered suitable for engraving purposes than for any qualities of their own. Among the woods so exhibited were *Backhousia myrtifolia*, *Hymenosporum flavum*, *Xanthoxylum brachyanthum*, *Acacia Cunninghami*, *Duboisia myoporoides*, *Dysoxylon Fraserianum*, *Gmelina Leichhardtii*, *Hemicyclia australasica*, *Weinmannia rubifolia*, *Eugenia myrtifolia*, *Pentaceras australis*, and others. Amongst fibres and fibrous barks was the bark of the small-leaved nettle-tree (*Laportea photiniphylla*), also a fishing-net, cordage, and a dilly bag made from the fibre by the aborigines of the northern coast districts. The collection from New Guinea exhibited in this Court was of considerable interest. The utilisation of the bony seed shells of *Pangium edule* for decorating the skin drums is one not seen by us before. The seeds produce a rattling sound when shaken similar to those of *Thevetia nereifolia*, which are used for like purposes in British Guiana.

South Australia.—The centre of attraction here was undoubtedly the scene on the Murray River wherein the habits of the aborigines were depicted. Wool figured largely, and the applications of emus' eggs for a great variety of purposes were fully illustrated. A good collection of small specimens of the woods of the colony was shown, as well as a collection of fruits and seeds.

Western Australia.—A fine collection of the timbers of the colony was exhibited in this Court, and outside near the basin adjoining. The principal woods shown were jarrah (*Eucalyptus marginata*), and karri (*E. diversicolor*). Of the former, one of the principal attractions in the Court was a log, some seven feet long, over four feet in diameter, and weighing nearly five tons, carefully polished on one end to show the cross section, and in the middle to show the longitudinal structure. The wood has a very fine deep red colour, and "for the durability of its timber," Baron Mueller says, "is unsurpassed by any kind of tree in any portion of the globe." When carefully selected and dried, it is proof against the attack of teredo, termites, or any other wood-borers. It is consequently in great demand for jetties, piles, railway-sleepers, fence posts, and all kinds of underground work, as well as for planking and frames of ships. This fine block of wood, and a fine slab or counter-top of figured jarrah and other West Australian woods, have been presented to the Museum of the Royal Gardens, Kew. Amongst the plants exhibited as being used for tea by the natives were the following:—The leaves and flowers of *Verticordia pennigera*, known, it is stated, to the settlers in the earlier days of the colony, and used medicinally. The taste is said to be similar to Chinese tea. Another kind of native tea proved upon examination to be furnished by *Kunzea Muelleri*.

Queensland.—Of vegetable products exhibited from this colony the collection of woods was the most noteworthy, not only for the number of species, but for the care shown in their selection and preparation. The two enormous trunks of cedar (*Cedrela Toona*), each some fifteen feet high, and one with a girth of twenty feet five inches, will as long be remembered for their majestic size by those interested in tree growth as the number and brilliancy of the opals will be remembered by those interested in gems.

New Zealand.—Next to the collection of birds and minerals, the timbers of New Zealand held a prominent place, and the furniture made from the most important and beautiful woods, such as mottled kauri (*Dammara australis*), and totara (*Podocarpus totara*) was well illustrated. The beauty of these woods is so great that it is remarkable they should still remain comparatively unknown amongst cabinet-makers in this country.

Cape of Good Hope.—The centre of attraction in this Court was undoubtedly the diamonds and diamond-polishing. Of the vegetable products a collection of native medicinal plants was shown, and their uses were well described in the catalogue of Cape exhibits, and for the most part are to be found also in Pappe's *Floræ Capensis Medicæ Prodromus*. There was also a very fine collection of well-seasoned and polished wood slabs, amongst them being Outeniqua yellow-wood (*Podocarpus elongatus*), an extremely valuable, fine-grained wood of a light yellow colour, useful for furniture, planks, flooring-boards, beams, &c. One slab of this fine wood—which was almost entirely hidden during the Exhibition by a counter being built over it, and measures about twenty feet long by five feet in diameter—has been presented to the Kew Museum, together with a fine set of other Cape woods, many of which might become useful in this country were they better known, notably the stinkwood or laurel wood (*Oreodaphne bullata*), a dark-coloured wood much resembling walnut in appearance, but heavier and considerably stronger, so that it has been recommended quite recently for gun-stocks. In the colony it is very highly prized for nearly every kind of work connected with building and cabinet-making, being little inferior if not equal to teak in strength and durability.

Natal.—Raw vegetable products largely predominated in this Court. Sugar, maize, tea, and tobacco were the principal staples. The cultivation and manufacture of tea is a new industry for Natal, and the result is that an article of very good quality has been produced, Natal tea having been on sale during the period of the Exhibition and well spoken of, so that there seems every probability of a future trade in this article with Natal. Amongst tanning materials we noticed the root, both entire and broken, of the Elands Bontjis (*Elephantorhiza Burchellii*), which has attracted some attention of late as a valuable tanning material. Preserved native fruits, such as granadilla (*Passiflora maliformis*), papaw (*Carica Papaya*), amatungulu (*Carissa grandiflora*), and others, were exhibited, as well as a variety of hard woods, many of which were without scientific names.

West African Settlements.—Under this head was included the Gold Coast, Lagos, Gambia, and Sierra Leone. The exhibits consisted largely of raw products of both the vegetable and animal kingdoms, together with some native manufactures, such as textiles from indigenous palm fibre or grasses, carvings in wood, &c. Oil seeds were shown in variety as well as in bulk, and notable amongst them were the kernels of *Elais guineensis*, malukeh seeds (*Polygala rarifolia*), which only occasionally finds its way to this country, physic nuts (*Jatropha Curcas*), benniseed (*Sesamum indicum*), and others as well known. Some very large balls of rubber were exhibited from Sierra Leone, and some fine masses of a kind of gum copal from the Gold Coast.

Ceylon.—Vegetable products abounded in this Court. On the walls were exhibited no less than 362 specimens of native vegetable drugs, got together by the Director of the Royal Botanic Gardens, Peradeniya. A very fine series of planks of the principal useful or ornamental timbers were exhibited, amongst them being tamarind, satinwood, ebony, calamander, and nedun (*Pericopsis mooniana*). The most attractive of the Ceylon woods is certainly calamander, but this is said to be now extremely scarce, and as it is of slow growth, the supply is very limited. Satinwood trees are common "in the northern, eastern, and north-western forests, but the proportion of these which yield 'flowered satinwood' is very small, and this description of wood is therefore comparatively high in price." Notwithstanding this scarcity of "flowered satinwood," several of the show-cases which contained the exhibits of tea, cardamoms, &c., and some of the barrels containing coffee, were of flowered satinwood. The Ceylon collection on the whole was one of particular interest.

India.—The extent of space occupied by our Indian Empire, and the varied and interesting character of the exhibits, will long be remembered. The contents of the art courts do not come within our notice, but there was sufficient material in the Economic Court for an extended notice. Space, however, will not allow us to say more than a few words on the unrivalled collection of the raw products of India—such a collection, indeed, as in all probability was never brought together at one time before. In such a collection it would be impossible to individualise any of the exhibits—those most striking, such as the bamboo bridge, will remain fresh in the memory—but it is in such details as the individual contents of the several shops that the interest of the economic botanist lies. To obtain any idea of the contents and value of the Indian Economic Court, we must refer our readers to the recently-issued "Special Catalogue of Exhibits," a large portion of which has been compiled by Dr. Watt, who had charge of the Economic Court during the Exhibition. This catalogue is a valuable and interesting record of one of the most important sections of the whole Exhibition.

We cannot close these notes without saying a word in commendation of the excellence of most of the catalogues, especially those of Ceylon and the Cape of Good Hope.

Museum, Royal Gardens, Kew

IPECACUANHA CULTIVATION IN INDIA

THE following note is from a letter which I have received from Mr. Gammie, who has charge of the cinchona plantations of the Bengal Government at Darjeeling. The facts are of considerable biological interest, as showing that amongst closely connected forms, which can scarcely be distinguished by palpable morphological differences, there may yet be unobvious constitutional distinctions which in the struggle for existence may determine the survival and ultimate dominance of some one form in particular.

The facts are also perhaps interesting in another way. To any one who will be at the pains to turn up vol. vii. of NATURE, p. 6, it will be amusing to see the sequel which the chance of circumstance has brought to one branch of a long-burnt-out controversy.

W. T. THISELTON DYER

Royal Gardens, Kew, December 13

"I don't think I ever told you the final results from our ipecacuanha-growing experiments, but do so now.

"Our original stock of plants came from Kew and Edinburgh—the great majority from Edinburgh. The few plants from Kew differed a good deal in appearance from the Edinburgh lot, which, again, differed greatly from each other. All the Kew plants were of one sort, which we named, from the start, the Kew variety. It was rougher in the leaf than the Edinburgh sorts, and not so strong-growing while under glass.

"After we had satisfied ourselves that we could make nothing of ipecacuanha, from a commercial point of view, we put all the plants out in the open, under shade, and let them take their chance. By this time we had all the sorts mixed up together; and as we had originally at least ten Edinburgh plants for each one of the Kew sort, and the Edinburgh lot had, besides, been much the stronger growers under glass, the Kew plants formed less than 5 per cent. of the whole. But very soon the Edinburgh sorts began to disappear, until, in the course of a year or two, there was not a single plant of one of the Edinburgh varieties alive, whilst almost every plant of the Kew variety lived. Of it, at the present moment, we have a good stock, and in one place, at 1400 feet elevation, under the shade of living trees, we have plants, which were put out many years ago, in the most perfect health, but unfortunately their growth has been so slow as to render the prospect of any profitable return from them almost hopeless. Still it strikes me that, in places geographically better situated for ipecacuanha-growing than Sikkim, this particular variety may succeed, although other sorts may have failed. Probably our ipecacuanha experiments may prove another instance of the folly of giving up the cultivation of new crops as hopeless until the most exhaustive experiments have been carried out. It may be that there are even hardier varieties of ipecacuanha than the 'Kew variety' to be found."

SUNSPOT OBSERVATIONS IN HUNGARY[1]

THE Observatory, of which the first volume of Publications is now before us, was founded by Cardinal Haynald in 1878 in connection with the archiepiscopal gymnasium at Kalocsa in Hungary. Preliminary geodetic operations, of special importance as supplying an independently determined point of reference for the Hungarian survey, with the examination and adaptation of instruments, cost much time and labour; so that only a fragmentary part of the energy of the establishment has hitherto been available for purely astronomical work. The Director, however, Dr. C. Braun, has wisely embraced the rule of concentration which governs most successful campaigns, and is hence enabled to present, in lieu of a multitude of scattered and perhaps useless observations, the connected results of four years' solar study, unpretending in aim, but thoroughly well executed, and developed with much clearness and not a little originality. The time, it is true, has somewhat gone by for visual solar work of the kind here described; and Dr. Braun, like all other astronomers, is getting ready his camera. Still, it is well worth while to consider what has been learned—even at a somewhat disproportionate cost of labour—by graphical delineation pursued through fifty consecutive solar rotations.

The instrument employed was the smaller of two excellent Merz refractors possessed by the Kalocsa Observatory. It is of four Paris inches aperture, is equatorially mounted, and appears to possess uncommonly fine definition. To its eye-end was fitted an apparatus invented and constructed by Dr. Braun himself, by means of which an image of the sun 22 centimetres in diameter was projected, after total reflection from a right-angled prism, upon a sheet of drawing-paper. In this way nearly 5000 drawings of spots were executed during the years 1880 to 1884. For their reduction two expeditious methods—one graphical, the other computative—were devised; and the resulting heliographical latitudes are rendered strictly comparable with those derived by English observers, through the application of a small correction due to a difference in the adopted elements of the solar rotation. Now that sunspot observations have become cosmopolitan, it seems indeed a pity that there should not be unanimity on this point among astronomers. Dr. Braun conforms, however, to the solar prime-meridian chosen at Greenwich, so that the longitudes given in his maps practically coincide with Greenwich longitudes.

The highest grade of accuracy was not aimed at in these observations. Their object was the collection of materials for studying the processes of spot-formation and the relation of spots to prominences, with side-glances towards a possible, but every year less and less probable, transit of "Vulcan." The determination of the solar rotational elements, or of the minute changes of latitude of spots, was left to observers provided with the means of executing refined micrometrical measurements. Nor was the estimation of maculated area attempted. Yet with all these limitations, much of interest remains to be gathered from the paper before us.

The results are portrayed in fifty maps, each representing the aspect of the sun's surface between the parallels of 40° north and south, during one synodical rotation. The indication of the solar meridians which on successive days were central at mean mid-day (Kalocsa time) renders it easy to trace the fluctuating appearance of the actual visible disk throughout each period. The maps further contain two long sinusoid curves—one denoting the heliographical latitude of that point on each meridian of which the position-angle on the east limb was 90°, the other showing the latitude of the points similarly situated on the west limb. Hence the position-angle of any given spot as it traversed either edge of the sun can at once be deduced—a datum obviously much facilitating inquiries into the connection of spots with prominences.

To each map corresponds a table, in which, besides the heliographical position of each spot, something of its history and peculiarities is set forth—the number of times it was observed, the epochs of its appearance and disappearance, with a general description of its size and shape. Especial interest attaches to a table in which Dr. Braun

[1] "Berichte von dem Erzbischöflich-Haynaldschen Observatorium zu Kalocsa in Ungarn." Von Carl Braun, S. J. (Münster i. W.: Aschendorff, 1886.)

has separately collected particulars of sixty-one spots, held, with more or less of probability, to have presented themselves afresh after making the circuit of the sun, and hence to be available as guides to the period and law of its rotation. From these data he constructed a curve (Plate XVI. Fig. 2) showing the variations in the rate of spot-displacement with varying latitude, the perfect symmetry of which on either side of the sun's equator testifies to the absence of any systematic difference in this respect between the hemispheres. From the curve were derived three distinct formulæ of the solar rotation, all fitting perfectly with the observations within the parallels of 30°, but diverging widely in their results for high latitudes. For example, No. I. gives for the region close to either pole a period of just 33 days; No. III. of a little over 40; No. II. of 55·8 days. From Carrington's formula, Dr. Braun deduces a polar period of 30·86 days; Faye's implies one of 32; Spörer's actually reverses the direction of change beyond the spot-zones, indicating a recovery of velocity towards the far north and south, and a period, in latitude 90°, of no more than 25·1 days—about the same which prevails in parallels of 10°. It may be worth remarking, as at least a coincidence, that almost precisely this rate of motion was inferred by Father Secchi (very doubtfully, it is true) from observations of relatively stable prominences near the pole. Nevertheless, a survey of the discrepancies tabulated by our author can hardly fail to inspire a profound distrust of empirical formulæ, and still more of the risky process termed "extrapolation."

The swiftest-moving spot noted by the Kalocsa observers was situated 1° 20′ north of the equator; its estimated daily displacement of 868′ bringing about the completion of its circuit in 24·88 days. The most sluggish was in south latitude 29° 38′, and gave a period of 26·5 days. As might have been expected, considerable irregularities are apparent; yet not more than might reasonably be set down to uncertainties of observation. A much higher degree of accuracy must, however, be reached before the mean rate of motion proper to each parallel can be at all satisfactorily ascertained. This mean rate is itself, in Spörer's view, subject to cyclical change; and his observations during the years 1861-1871, as compared with Carrington's during seven preceding years, disclosed persistent differences not easily accounted for. Dr. Braun's results, on the other hand, agree quite as well as could be expected with those of the English observer. A further complication is introduced by what may be called the individual caprices of spots. Each spot has probably a velocity of transport peculiar to itself, depending upon the circumstances of its origin; this velocity is certainly subject to accelerations connected with the processes of its development. These accelerations (for the change of motion is always in a *forward* direction) are shown, in Prof. Spörer's recent communication to the Physical Society of Berlin, to be very considerable; they are beyond question highly significant; yet they emphasise our disadvantage in being compelled to rely upon such unstable phenomena for all our knowledge regarding that most important datum—the rate of the sun's revolution on its axis.

The Kalocsa solar observations were made at a critical period. They cover the whole of the prolonged maximum which culminated near the close of 1883, and disclose or confirm very satisfactorily some of its characteristics. Dr. Braun has depicted in a remarkable curve the progressive changes in the mean latitude of the spot-zones during the years 1880-84. Their continuous approach to the equator at once strikes the eye; but superposed upon the line of uniform descent is a series of minor oscillations with a period of about a year, and an amplitude of fully 2°, which seem too regular and strongly-marked to be the mere effect of accident. This feature is quite novel and deserves attention.

The general rule that the long series of spots comprised within each cycle break out first in high latitudes, and become extinct close to the equator, was first observed by Carrington, and may now be regarded as fully established. Ordinarily, the maximum occurs when the mean latitude of the zones is 16° or 18°, the energy of the disturbance diminishing as they close further in. But the retarded character of the recent crisis was significantly attested by the fact that it did not reach its height until the closing in had proceeded much further than usual. In 1882, when the maximum was due, the average latitude of spots was (from Dr. Braun's curve) about 16°; whereas, at the close of 1883, when the maximum actually occurred, it was no more than 11°. It would seem as if the punctual and duly prepared completion of the outburst had been frustrated, and its stored-up energy spent upon an abnormal protraction of the maximum.

It might even be said that the perturbation thus indicated affected chiefly, or solely, the southern hemisphere of the sun. Although the respective sum-totals of spots observed at Kalocsa north and south of the equator eventually almost exactly balanced each other, large temporary discrepancies were manifest. The northern hemisphere displayed in 1880 an excess of activity, still more conspicuous in the ensuing year. Southern spots, on the contrary, outnumbered northern in 1882 to the extent of 8 per cent., and in 1883 in the proportion of nine to five. Dr. Braun adds the remark that each hemisphere would almost seem to have completed its cycle of change independently of the other, the northern maximum having occurred late in 1881, while the southern was postponed for two further years. The cause of perturbation should, in this view, be localised in the southern hemisphere.

A. M. CLERKE

NOTES

ON November 10 last, an important meeting of intercolonial delegates was held at the rooms of the Royal Society, Sydney, for the purpose of forming an Australasian Association for the Advancement of Science. There were delegates from all the principal scientific Societies of Australia, and they seem to have had no difficulty in arriving at a decision on the questions they had met to discuss. On the motion of the chairman, Mr. Russell, it was agreed that an association of the scientific Societies of Australasia should be formed under the name of "The Australasian Association for the Advancement of Science." It was also resolved that the rules of the British Association should be adopted, and that the first meeting of the Australasian Association should be held in Sydney in the first week of September 1888. This date was fixed because it will be the hundredth anniversary of the foundation of the colony of New South Wales.

MR. H. N. RIDLEY, of the British Museum, intends to make an expedition to the island of Fernando Noronha for the purpose of investigating its natural history. The funds for the expedition have been supplied by the Royal Society, and Mr. Ridley hopes to be able to start at the end of February. The marine flora and fauna were collected by the *Challenger* Expedition, but owing to the fact that the island is a Brazilian penal settlement, no naturalists have hitherto been permitted to make collections therein. The Trustees of the British Museum have obtained from the Emperor of Brazil the necessary permission for Mr. Ridley's exploration of the island, which, from what little is known of it, and from its geographical position, promises to be of exceptional interest from a natural history point of view.

THE death is announced, at Victoria, British Columbia, of Dr. W. F. Tolmie. Dr. Tolmie's name has been favourably known to ethnologists for many years in connection with his researches respecting the Indian tribes of British Columbia and neighbouring parts of the Pacific coast, where he has been almost continuously resident since 1833. Dr. Tolmie was a native of Inverness, but in 1832 accepted an appointment as medical officer to the Hudson's Bay Company at Fort Vancouver on the Columbia River, and subsequently became a chief factor in the Company's service. Information supplied by him to Mr. George Gibbs and other ethnologists has appeared in various publications. In 1884 he published, in conjunction with Dr. G. M. Dawson, a nearly complete series of short vocabularies of the principal languages spoken in British Columbia. He has had for many years a larger work in contemplation on the traditions and folk-lore of the same tribes, but the materials for it were not complete at the time of his death.

CHARLES SHALER SMITH, the distinguished engineer, died at his home in St. Louis, Mo., on December 19, 1886. He had been suffering from the effects of a fall, which resulted in serious injuries. From the first his case was considered very grave, but his great vital powers enabled him to keep up for two years.

MR. CLEMENT WRAGGE, late of Ben Nevis Observatory, and now of Adelaide, is to be appointed Meteorologist to the Government of Queensland.

YESTERDAY Prof. A. W. Reinold, F.R.S., delivered at John Street, Adelphi (the Society of Arts), the first of the usual short course of lectures adapted for a juvenile audience. The subject was "Soap Bubbles." The second lecture will be given on January 12.

THE lectures founded by Sir Thomas Gresham will be read to the public gratuitously on the following days, at Gresham College, Basinghall Street, in the subjoined order, beginning each evening at 6 o'clock:—Rhetoric (Mr. J. E. Nixon), January 18, 19, 20, and 21; law (Dr. Abdy), January 25, 26, 27, and 28; geometry (Dean Cowie), February 1, 2, 3, and 4; physic (Dr. Symes-Thompson), February 8, 9, 10, and 11; divinity (Dean Burgon), February 15, 16, 17, and 18; astronomy (the Rev. E. Ledger), February 21, 22, 24, and 25; and music (Dr. H. Wylde), March 1, 2, 3, and 4.

THE complaint is frequently heard that natural science does not get adequately encouraged in Oxford. Six weeks ago a notice was issued by Queen's College that an examination would be held on March 1, 1887, for the purpose of filling up various Scholarships and Exhibitions, including one Scholarship for mathematics and another for natural science. This notice was inserted in various newspapers, of which copies were sent to upwards of a hundred schools in England. The result is that *one* candidate has signified his intention of offering himself for examination in natural science. No doubt there will be at least ten candidates for the vacancy in mathematics, and twenty for each vacancy in classics. This certainly does not show a demand for natural science scholarships in excess of the supply.

ON December 9 the Council of the College of Surgeons adopted, and ordered to be entered on the minutes, a report from the Committee, recommending that the Committee's powers should be enlarged, with a view to the extension of the museum and the library, and the addition of work-rooms. It was also recommended that the Committee should receive power to take other improvements into consideration, and to inquire to what extent an increase of the staff would be rendered necessary by the proposed changes. The improvements, it is believed, would be paid for out of the Erasmus Wilson legacy. The scheme is likely to meet with some opposition, and before finally deciding on a matter of so much importance the Council would do well, as the *British Medical Journal* suggests, to submit its plans to the Fellows.

WE regret to notice that objection is being made in Hong Kong to the expense of publishing in the official gazette the Monthly Weather Reports of the Observatory there. These tables, which have frequently been noticed in these columns, contain the usual statistics of evaporation, radiation, the relative humidity and tension of aqueous vapour, the classification of clouds, and other meteorological details. The local critics say that these are of no practical value; but they surely forget that similar tables are published by every Observatory in the world. The Tokio and Siccawei establishments, to select two which are nearest to Hong Kong, publish periodically the same meteorological statistics, and it is therefore sincerely to be hoped that Dr. Doberck will be permitted to pursue his arduous and useful labours. The colony handsomely voted a sufficient sum for an Observatory a few years ago without question, and the work which it has since done is appreciated in Europe. Only a few weeks since we printed a paper by Dr. Doberck on the typhoons of the China seas, which was essentially and directly practical, for it told the mariner of the various classes of these storms, their direction, and course, and the time at which they are most prevalent. It further explained how vessels caught in these typhoons may best minimise or escape altogether from their evil effects. All this information, the value of which for the protection of life and property, can be appreciated nowhere better than in Hong Kong, with its enormous shipping trade, is obtained only by the careful and sedulous collection and collation of statistics. The physical position of Hong Kong renders its Observatory one of considerable importance in meteorological science, and it is the duty of the colonial Government to see that the institution is not allowed to decline from the high standard which it has already attained.

THE ideas of some Americans as to the education of women seem to be very far ahead of those which still prevail in this country. At Northampton, near Amherst, an observatory is being built by the Trustees of Smith College for young women. Mr. David P. Todd, Director of the Amherst College Observatory, has lately devoted much time to the plans for the construction and equipment of this building, taking care that it shall be thoroughly fitted for the purposes of collegiate instruction, and that it shall contain ample facilities for research.

A SOCIETY for the promotion of the higher education of women has been founded in Japan, under the presidentship of the Prime Minister, and with the support of various influential foreign and Japanese gentlemen. Besides regular courses of instruction which will be provided, special courses of afternoon lectures will be delivered by the professors of the University. The whole institution will be under the control of a foreign lady principal, assisted by two or more foreign lady teachers. Although female education in Japan has already reached an advanced stage, this appears to be the first attempt to provide for the higher education of women, as understood in European countries.

THE late Mr. Greenleaf, the Boston hermit, left the whole of his fortune—probably amounting to five hundred thousand dollars—to Harvard College. The conditions imposed by him are said to be not unreasonable, but it would have been better, as *Science* urges, if he had imposed no conditions whatever. Wealthy men who think of bequeathing money to learned institutions apparently find it hard to realise that the authorities of those institutions are likely to be the most competent judges of the way in which the money should be spent. The needs of Harvard College were certainly not so well known to Mr. Greenleaf as to its President and Faculty.

THE other day *Science* commented on the fact that advertisements calling for applications for vacant Chairs in leading educational institutions are often inserted in educational and literary journals in England. This is never done in the United States. There were no fewer than forty applications for a recent vacancy in a prominent American college, and if the appointment had been advertised, the number would no doubt have been very much larger. *Science* is of opinion that American colleges lose nothing by declining to follow the English example in this matter, since in the case of every important college "the president and trustees keep their eyes continually open, and when a vacancy occurs they are pretty sure to know who is the best man for the place, or, in any event, they have made up unconsciously a short list from which the selection is to be made." A distinct advantage of the American plan is that governing bodies are not troubled with the importunities of persons who wish to be appointed to positions for which they are wholly unsuited.

THE Wagner Free Institute of Science, Philadelphia, has issued a valuable report, by Mr. Angelo Heilprin, on his explorations on the west coast of Florida and in the Okeechobee Wilderness. Mr. Heilprin is of opinion that the whole State of Florida belongs exclusively to the Tertiary and post-Tertiary periods of geological time, and consequently, as a defined geographical area, represents the youngest portion of the United States. There is not, he thinks, a particle of evidence supporting the coral theory of the growth of the peninsula. Sedimentation and deposition along this portion of the American coast appear to have been practically unbroken or continuous, as is indicated by the gradational union of the different formations, and the absence of broad or distinct lines of faunal separation. The elevation of the peninsula, especially in its more southern parts, seems to have been effected very gradually, judging from the perfect preservation of most of the later fossils, and the normal positions—*i.e.*, the positions they occupied when living—which many of the species still maintain. There is evidence that before its final elevation a large part of the peninsula was for a considerable period in the condition of a submerged flat or plain, the shallows covering which were most favourably situated for the development of a profuse animal life, and permitted of the accumulation of reef-structures and of vast oyster and scallop banks. The present submerged plain or plateau to the west of the peninsula may be taken to represent this condition. Fresh-water streams, and consequently dry land, existed in the more southern part of the peninsula during the Pliocene period, as is proved by the inter-association of marine and fluviatile mollusks in the deposits of the Caloosahatchie. Mr. Heilprin holds that the doctrine of evolution receives positive and most striking confirmation in Florida, because the modern fauna of the coast is indisputably a derivative, through successive evolutionary changes, of the pre-existing faunas of the Pliocene and Miocene periods of the same region; and the immediate ancestors of many of the living forms, but slightly differing in specific characters, can be determined among the Pliocene fossils of the Caloosahatchie. He is also convinced that man's great antiquity on the peninsula is established beyond a doubt, and he suggests that the fossilised remains found on Sarasota Bay, now wholly converted into limonite, may represent the most ancient belongings of man that have ever been discovered.

AN interesting paper on the sub-genus Cylinder (Montfort) of Conus, contributed by Mr. J. Cosmo Melvill, M.A., F.L.S., to the tenth volume of the third series of Memoirs of the Manchester Literary and Philosophical Society, has been reprinted. Mr. Melvill has much to say about the *Conus gloria maris*. This exquisite shell is "prominent among all its kindred for beauty of shape and excellence of pattern;" and "the reticulations are so fine as to defy the skill of the lithographer." The land of its nativity is Jacna, island of Bohol, Philippines, where the late Mr. Hugh Cuming found two examples, one very juvenile, scarcely more than an inch in length. Mr. Cuming tried hard to find other specimens, employing all the available natives in dredging expeditions; but his efforts were unsuccessful. It is said that the original very circumscribed locality has been annihilated by an earthquake, and Mr. Melvill thinks that this is not improbable. Only twelve specimens are known to exist. Five are in this country, and one of them is in Mr. Melvill's collection at Prestwich. Another—perhaps the finest specimen known—is in the collection which belonged to the late Mrs. De Burgh, and three are in the British Museum collection at South Kensington. A good example was bought by Mr. Lovell Reeve in 1865 for the Melbourne Museum.

WE have received a "List of the Macro-Lepidoptera of East Sussex," compiled by Mr. J. H. A. Jenner, F.E.S., Lewes. It is reprinted from the Proceedings of the Eastbourne Natural History Society. East Sussex, according to Mr. Jenner, is probably one of the richest, in number of species, in the country. This he attributes to the southern latitude of the district and its varied characteristics—its downs, marshes, extensive woods and forests, and its sea-coast. Some parts of East Sussex have been well worked by entomologists, especially near the larger towns, but little is known of some of the outlying districts.

AMONG the numerous forms of fungus which live upon higher plants (many of which are so detrimental to their hosts) are some, it is now believed, which live with these on terms of mutual assistance. Frank found that the young root points of some of our forest trees, as the beech and the oak, are covered with a coating of fungus (probably belonging to the truffle or allied family), which seems to help in the nutrition of those trees. Another interesting case is that of fungi which live with orchids, and whose mode of propagation has lately been established by Herr Wahrlich (*Botanische Zeitung*). The fungus appears in the outer cells of the root tissue in the form of yellow bladder-like balls (of the nature of *haustoria* or suckers) surrounded by numerous filaments. It works no perceptible harm to the plant, but on the contrary it is thought that, especially in the case of orchids which live on the humus of woods, the fungus probably transforms the humus matters into such as are more easily utilised by the orchid, thus doing it a physiological service. The fungi observed by Herr Wahrlich belong to the family of *Pyrenomycetes*, and the genus *Nectria*.

THE amount of free carbonic acid in the ground has been lately shown by Prof. Wollny (we learn from *Naturforscher*) to depend, on the one hand, on the factors of decomposition of organic substances (heat, moisture, porosity), as affected by the physical nature of the ground and its covering; on the other hand, on the resistance which the ground presents, according to its mechanical state, to the escape of the gas. Ground-air seems to have most carbonic acid when the ground is at a slope of about 20°. Slopes facing south have most carbonic acid; those facing north, least, though the difference is not great, as the two principal factors, heat and moisture, largely counteract each other. In drought, ground facing north has more carbonic acid. With equal quantities of organic matter there is more carbonic acid, the more finely granular the ground; and such ground hinders movement of the gas downwards as well as into the atmosphere. The air in ground shaded by living plants has considerably less carbonic acid than that in bare ground, and in the latter it has less (in dry years, not in wet) than in ground covered by dead parts of plants.

IN lecturing upon the "Denizens of the Aqueous Kingdom" on Friday last at the Royal Aquarium, Mr. August Carter referred to deformities that exist among fish. In 1885 and 1886 he had examined many thousands of trout and salmon fry at South Kensington on their emerging from the ova, and found one case of deformity in every thousand, and one case of monstrosity, such as twin and dual-headed fish, in every four thousand. From observations he had made at the South Kensington Aquarium and elsewhere, the lecturer concluded that certain fish, such as the carp and perch, have the power of communicating with one another.

WHILST collecting fish ova from the River Colne for the hatchery at the Delaford Fish Culture Establishment, the water-bailiffs found an "egg-bound" trout, that is, one that had died through being unable to extrude its eggs. It was brought to Mr. W. Oldham Chambers, who on examination found the ova to be thoroughly healthy, although the fish, judging from its decomposed state, must have been dead about three weeks. He at once obtained a milter, and succeeded in impregnating the ova, which appear to be quite healthy and capable of incubation. The spawning season has been greatly retarded by the extreme severity of the weather.

WE have received the first number of the *Cycling Budget*, the editors of which undertake to keep cyclists "thoroughly well posted in every imaginable topic which may be of service to them." There are to be careful analytical descriptions of every new or modified type of machine as it comes into the market. The *Budget* advocates the building of a club-house for cyclists in London. In America, it appears, there are magnificent club-houses for "the votaries of the pastime."

DURING the year ended October 31, 1886, the total quantity of steel and ingot iron made from phosphoric pig was 1,313,631 tons, of which 927,284 tons were ingot iron containing under ·17 per cent. of carbon. As compared with the make of the previous twelve months, there was an increase of about 368,314 tons. The total quantity produced represents about 394,000 tons of slag, containing from 30 to 35 per cent. of phosphate of lime. Most of the basic slag made in Germany is finely ground, and used in place of superphosphates.

M. ALFRED MARCHE, who has already been despatched on more than one scientific mission to distant regions on behalf of the French Ministry of Public Instruction, left Marseilles on the 19th ult., on a similar errand, for the Marianne Islands.

M. THOUAR's expedition to solve the question of the navigability of the Pilcomayo, and its suitability as a trade route between Bolivia and the eastern parts of South America, has had to be postponed so far as the upper waters are concerned, owing to the refusal of the Bolivian Government at present to supply its share of the funds for the undertaking. Writing, however, from Suere on October 22, M. Thouar reports that the Bolivians have confided to him a mission of exploration in the same regions. He is to cross the Bolivian Chaco and survey it, with a view to discovering a land route for trade, and also to make a scientific investigation of the territory on the right bank of the Paraguay, directing especial attention to its capacity for cultivation and to the methods by which immigration should be encouraged. M. Thouar was to start on this mission about November 18.

THE *Annuaire pour l'An* 1887, issued by the Bureau des Longitudes, Paris, contains much astronomical and other scientific information, arranged in a convenient form. The work is carefully edited, and has been considerably enlarged, by M. Loewy, one of the members of the Bureau.

THE current number of the *Memorie della Società degli Spettroscopisti Italiani* contains a good portrait of the late Alessandro Dorno, with a brief sketch of his career. Dorno was born at Asli on February 13, 1825. He had scarcely taken his degree at the University of Turin in 1848 when he was appointed Professor of Mechanics at the Military Academy there. In 1865 he was made Professor of Astronomy at the University of Turin and Director of the Observatory. Many papers by him appeared in the Transactions of the Turin Academy of Sciences, and he was a frequent contributor to the various scientific journals. In 1874 he took part in the scientific expedition to India for the observation of the transit of Venus. He died at the Villa di Borgo, San Pietro, near Turin, on August 19, 1886.

WE have received Parts 16-20 of the "Länderkunde des Erdteils Europa," which is being issued at Leipzig and Prague. This admirable work is edited by Dr. A. Kirchhoff, who has secured the co-operation of many eminent geographers. There are numerous illustrations, all of which are carefully executed.

WE print to-day an abstract of an excellent paper on "The Use and Equipment of Engineering Laboratories," by Prof. A. B. W. Kennedy, M.Inst.C.E., read at the ordinary meeting of the Institution of Civil Engineers on Tuesday, December 21, 1886.

WITH regard to the postscript to his letter on "Electricity and Clocks," in our last number (December 30, 1886, p. 198), Mr. Henry Dent Gardner writes to us that it is the weak spring, not the hammer, which should be kept away from a banking.

THE additions to the Zoological Society's Gardens during the past week include two Green Lizards (*Lacerta viridis*), a Slow-worm (*Anguis fragilis*), European, presented by Mr. R. M. J. Teil; a Yellow-footed Rock-Kangaroo (*Petrogale xanthopus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

THE ANDROMEDES, NOVEMBER 27, 1886.—P. F. Denza, writing in *Cosmos* under date December 2, gives the results of the watch maintained on the night of November 27 last at seven observatories distributed over the Italian peninsula. All the reports alike agree in showing that there was no repetition of the shower of 1885, the number of meteors observed being no greater than on an ordinary night, and of these the majority radiated from Perseus and Taurus, only very few from the radiant of the Andromedes. It follows, therefore, from these observations and those of 1873 and 1885, that the meteoric cloud giving rise to the shower is of comparatively small extent, but very dense. This fact tends to confirm the theory of the recent formation of the stream and of its origination in the disintegration of Biela's comet. The interval, thirteen years, between 1872 and 1885, corresponds to two revolutions of the comet; but the earth was in quite a different part of its orbit at the date of the intermediate return, and therefore no shower was witnessed.

THE REDUCTION OF THE POSITIONS OF CLOSE POLAR STARS FROM ONE EPOCH TO ANOTHER.—A paper containing a catalogue of 130 Polar stars for the epoch 1875·0, resulting from all the available observations made between 1860 and 1885, and reduced to the system of the Catalogue of Publication xiv. of the Astronomische Gesellschaft, has been communicated to the American Academy of Arts and Sciences by Prof. W. A. Rogers and Miss Anna Winlock. The first section of this work, giving an investigation of the methods of reducing the positions of close Polar stars from one epoch to another, has been published in the Memoirs of the Academy, vol. xi. part 4, No. 5. And Prof. Rogers chivalrously appends a note to the effect that his connection with the work is limited to the methods of discussion adopted, and to an examination of the numerical results obtained; and that beyond this all the work in the preparation of the paper has been done by Miss Winlock, who is entitled to all the credit therefor. By the laborious process of actual computation, taking the instance of Groombridge 1119—a star situated within 1° of the Pole, it is shown that it is impossible to obtain an exact agreement between the values of the precessional motion computed by Taylor's theorem and the corresponding values computed from the rigorous trigonometrical formulæ, in the case of such a star, when the time exceeds forty years. But it is also shown that the time at which the values derived from the development by Taylor's theorem begin to deviate from those derived from the rigorous formulæ may be extended many years by means of a secondary series, which represents the residuals between the exact co-ordinates and those obtained with any assumed limit to the terms of the series. The application of this principle to the case of Groombridge 1119 is explained, and the formulæ formed for reducing the stellar co-ordinates to any date between 1875 and 1955, and also between 1875 and 1755. The results obtained by Miss Winlock will doubtless be very useful to astronomers discussing the positions of close Polar stars.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1887 *JANUARY* 9-15

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on January 9

Sun rises, 8h. 6m.; souths, 12h. 7m. 20·2s.; sets, 16h. 9m.; decl. on meridian, 22° 6′ S.: Sidereal Time at Sunset, 23h. 24m.

Moon (Full) rises, 4h. 11m.; souths, 0h. 9m.*; sets, 8h. 3m.*; decl. on meridian, 18° 44′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′

GEOGRAPHICAL NOTES

THE latest news from Dr. Oscar Lenz is of much interest. Three letters have been received from him, the latest dated June last from Kasonge, a large Arab town, three days south-east from Nyangwe, on the Upper Congo. Dr. Lenz, it will be remembered, went out for the purpose of reaching Dr. Junker and Emin Bey. The latest rumours state that he has been compelled to abandon this object, and may therefore be soon heard of at Zanzibar. Dr. Lenz, in canoes furnished by the famous Tippoo Tip, journeyed up the Congo from Stanley Falls, taking fifty days by the way. This, however, included frequent stoppages. He found great changes had taken place since Mr. Stanley made his memorable voyage down the river ten years ago. Then there were few Arabs to be seen beyond Nyangwe, and the river over a great part of its length was peopled by natives, between whose villages the expedition had to run the gauntlet. Now Dr. Lenz finds the whole country practically in the hands of Arab and Zanzibari slavers and traders. The natives in many places have retired into the recesses of the forest, and large Arab settlements have taken their place at several points along the river. There is a constant traffic up and down the river between Nyangwe, or rather Kasonge, and Stanley Falls. Immense rice-fields occupy the swampy and unhealthy areas round these Arab settlements, and all round Nyangwe and Kasonge the country is covered with rice, and plantations of bananas and other fruits. Nyangwe is no longer the important centre it was in the days of Livingstone. It is an irregular collection of Arab settlements, covering a considerable area. Kasonge, three days' journey off further up the river, is, on the other hand, a large town, with broad streets and many well-built houses. This is the head-quarters of Tippoo Tip and other Arab traders, who have their agents for their ivory in Muscat and India. It is evident that we have here a great and increasing intrusion of a foreign element among the native population. In some cases the natives are on friendly terms with the Arabs, and in other cases hostile. At any rate the result will in the end be a very serious modification of the population over a great area of Central Africa, and a marked change in the face of the country by the introduction of rice and other exotic cultures.

MM. BONVALOT AND CAPUS, the French travellers in Central Asia, lately turned back by the Emir of Afghanistan, write to the French Geographical Society, giving some account of their recent journeys. They refer especially to the country between Teheran and Meshed, which they traversed in April last, and which, as they say, is so much frequented that no one thinks it worth while to observe its special features. They found it much cut up by broad rivers with pebbly beds, and irrigation canals which nourish the rare oases along the base of the Elburz Range. The travellers found themselves almost always in the steppe region, on the edge of an immense basin, the bottom of which is the "Khevir" or great salt desert. It is incrusted on the surface with a great quantity of saline crystals, especially soda and magnesia, which often spoil the water and render cultivation impossible. The flora, the fauna, and the geology are those of the steppe, and MM. Bonvalot and Capus make out that the region forms a geographical unit with Central Asia. Not a tree, not a bush even, unless a few garden fruit-trees, with willows and poplars along the canals, relieve the monotony of the country. From the bridge of Saugil to the Thian-Shan, going from west to east, such a thing as a forest is unknown.

HERR QUEDENFELDT, in a paper in the last number of the *Verhandlungen* of the Berlin Geographical Society, on a recent journey in Morocco, mentions a fact of some geographical interest. For more than two years a commission of three or four Spanish staff officers, with a colonel as chief, has been stationed at Tetuan, and have quite publicly been carrying out a topographical survey. They have in this way already surveyed a considerable part of the Garb region, as far as Tangier, Arsila, Laraish, Alkasar, and even Fez.

IN the December *Petermann*, Count Pfeil describes his journeys of exploration last year in the Ulanga and Ussagora regions, with a map. But the article which will attract most interest now—a melancholy interest in some respects—is the preliminary report of the late Dr. Fischer, on the expedition for discovering Dr. Junker; this, too, is accompanied by a map. Dr. Emil Jung continues his essay on the effect of the last Indian famine on the movements of the population, basing the discussion on the official census. A special part of the *Mittheilungen* has been issued, containing an elaborate and systematic index of the contents of the periodical for the ten years 1875-84, including ten annual volumes and eight supplementary volumes. By an ingenious system of colouring, a glance at the maps of the various continents shows that special maps have been published with the magazine during that period, what the scale of each is, at what part of the publication it is to be found, and whether the map is topographical, physical, geological, or statistical. These maps, with their variously-coloured lines, show, too, in a moment, what are the regions of the earth which have most engaged attention during the last ten years. In Europe the Balkan peninsula is covered with lines, in Asia the khanates, the Pamir, Tibet, and South-Western China, while the number of lines in Central Africa north and south of the equator form a veritable labyrinth. A rough idea of the work of every traveller in the last ten years could be formed from this outline map alone, as the name and occasionally the date are added in each case. The index and the maps give a bird's-eye view of the work of this famous geographical publication better than anything else can do, and we are glad to know that it begins a new decade full of youthful life and vigour, and with the prospect of a career of as much usefulness in the future as in the past.

Herr Niederlein, of Buenos Ayres, has been appointed Naturalist and Geographer to the Argentine-Brazilian Boundary Commission, on behalf of the Argentine Government, and he left in October last for the *rendezvous* of the Commission at Misiones. He has been engaged for sixteen months in the Ministry of Foreign Affairs of the Republic, working out the results of a previous journey, especially his surveys on the Uruguay and Parana Rivers and their main tributaries; these, however, did not rest on any astronomical observations, a defect which he hopes to remedy in the present journey. A careful geodetic survey of the frontier districts will be made, and a map of these and of the province of Corrientes will be published next year.

TASMANIAN FISHERIES

The Report for 1885 of Mr. Saville Kent, Superintendent and Inspector of Fisheries to the Tasmanian Government, contains a good deal that is of scientific as well as economic interest, as will be seen from the following extracts:—

(1) *The Oyster Fisheries.*—It affords me much gratification to inform you that considerable success has attended the experiments made in the direction of breeding oysters on the Government reserves and in private fisheries, upon the system advocated and explained in my last year's Report. This system consisted chiefly of laying "collectors," constructed of thin planks or split palings coated with cement, over the breeding oysters placed upon the beds. At the Government reserve at Little Oyster Cove, on a private bed at Great Oyster Cove, and on one at the Prosser's River on the East Coast, a considerable quantity of brood or spat has adhered to the collectors laid down, giving the greatest encouragement for a yet more substantial and commercially remunerative return resulting from the following out of the system upon a sufficiently extensive scale. The operations so far conducted have been furthermore productive of much valuable information concerning the breeding habits of the oysters of this colony that may be hereafter utilised in their artificial culture. Thus, last summer none of the collectors were placed on the beds until November, which is generally accepted, as is May in England, as representing the earliest month in which the spat or brood is liberated. From the size of the brood deposited on the collectors, as also by an examination from time to time of the parent oysters, it was, however, made evident that the greater portion of the spat had been already emitted before the collectors were placed over them. This circumstance indicates the desirability, in future years, of having at least a considerable portion of the collectors in position by the commencement of September. It is of interest to observe that the larger portion of the spat deposited, at both the Government reserve at Little Oyster Cove and on the private bed in the adjacent bay, was derived from the New Zealand oysters, thus demonstrating that that variety is suitable for acclimatisation in Tasmanian waters. Another important circumstance to be recorded of the Oyster Cove reserve is the fact that the spat thus obtained was attached exclusively to the cemented collectors, and in no case to the shells of the parent oysters or to the rocks, cultch, or other natural objects to which they customarily adhere; this fact of itself affords practical evidence of the efficacy of these collectors for the purpose for which they have been devised.

At the Government reserve at Spring Bay the collectors ordered were not supplied sufficiently early to intercept the fall of spat. At the same time the fall which took place, both in the reserve and also upon the public and private oyster-beds throughout the Spring Bay district, has been a very abundant one, the young brood adhering plentifully to the parent shells, mussels, cultch, stakes, and any other objects that afforded them a suitable fulcrum for attachment. With a continuance of this past season's rate of increase, and provided a sufficient amount of breeding stock is maintained on the reserves and private beds, it should not take many years for this locality to regain its original prominent position with relation to the oyster trade. At the present time the recovery of this district has advanced to such an extent that there has been no difficulty experienced in obtaining from it during the present season a stock of about 50,000 breeding oysters for laying down upon various private beds and the Government reserves. From the third Government reserve, established at the West Arm on the Tamar estuary, no substantial results have as yet been obtained, it having been found impossible to complete it and stock it with oysters in time to obtain last summer's fall of spat. A fourth oyster reserve is in process of formation at Little Swanport; and it is proposed, with the funds available for the purpose during the current year, to establish similar Government reserves in the following neighbourhoods, *i.e.* the Carlton River, Taranna, and Southport in the southern district; and at George's Bay, Port Sorell, and other favourable localities to be yet selected, on the north-eastern and northern coast-lines.

I am gratified to be able to report to you that there are already substantial prospects of accomplishing one of the most important objects of the establishment of the Government oyster reserves. At the time of their inauguration it was anticipated and intended that these reserves, in addition to fulfilling the part of nurseries for the propagation of oysters and the replenishment of the surrounding waters, should likewise constitute central stations for the assistance and encouragement of private enterprise in a similar direction, and by whose aid, if developed upon an extensive scale, the restoration of the oyster fisheries of this colony on a thoroughly substantial commercial basis would be greatly accelerated. One private bed with breeding oysters is already established in the vicinity of the Government reserve at Little Oyster Cove, one at Spring Bay, and another at the Prosser's River. Encouraged by the success of these undertakings, applications have been or are about to be made for the leasing of three more suitable areas for the same purpose at Spring Bay, for the same number at Great and Little Oyster Cove, and for others in the neighbourhood of Little Swanport, and at Port Sorell on the north coast.

The important operations connected with oyster-culture in course of progress at the newly inaugurated Fisheries Establishment at Battery Point are recorded under the following heading.

(2) *Fisheries Establishment, Battery Point.*—Since the date of my last Report, and in accordance with the recommendations therein made, suitable premises, including a residence, have been selected and are now rented by the Government at Battery Point for the development and maintenance of a Fishery Establishment. To this site the marine hatchery originally erected at Gore Street has been transported, and re-erected with various additions. The premises occupied include a sea frontage of about three hundred feet, allowing the location of the hatchery so close to the water's edge that the salt water necessary for the maintenance of a constant circulation through the tanks is pumped direct from the sea. The mechanical arrangements are at the same time so disposed that in the event of a storm or flood rendering the outside water temporarily unfit for circulation, the intake pipe can be disconnected, and the water circulated independently from a small reservoir beneath the building. The great advantages derived from the transport of the marine hatchery to its present site, next to the means now afforded for obtaining an unlimited supply of pure sea-water, are the facilities it has provided for constructing in connection therewith tidal ponds for the culture of oysters and marine fish generally upon the adjacent shore. For this purpose an area of about one acre has been inclosed with stakes wired together after the manner adopted for the fencing off of the Government oyster reserves, and within this inclosure two such ponds have been already constructed. In consequence of the circumstance that at ordinary ebb tide the water recedes from a large portion, and at spring tides from almost the entire extent of this inclosed area, the plan has been adopted of excavating these ponds for a foot or two below lowest tide-level, so that under any circumstances they contain an abundant supply of water. The nature of the ground upon the

foreshore inclosed has proved to be well adapted for the construction of these ponds, as immediately beneath a thin superficial covering of sand it is composed of pebbles and tenacious clay so firmly amalgamated as to almost resemble concrete ; any excavations made in this bed are consequently thoroughly water-tight. In the preparation of this site for the required purpose, it was found desirable to divert the course of that portion of the Sandy Bay Rivulet which formerly at low tide flowed over the area now occupied by the ponds. This has been accomplished by further excavating the main channel of the stream straight out to sea, and away from the area inclosed, and by interposing between the two a barrier or groin of rocks and tree-trunks, which has had the desired effect of accumulating along its course a natural sand-bank which effectually shuts off the water of the creek. One of the ponds constructed in the inclosure, measuring sixty feet long by thirty wide, is situated immediately beneath the hatchery, and serves as a reservoir for the constant supply of the tanks. This pond, being fenced round with wire netting, is further utilised for the storage and culture of a variety of edible fish in addition to oysters. With each ebb and flow of the tide the water in this pond is more or less completely renewed, and the fish under these conditions are found to thrive remarkably. A list of the edible species of fish that have been cultivated in the pond and tanks since the establishment of the fishery at Battery Point—that is, between the months of February and July 1886—is herewith annexed.

1. Native Salmon (*Arripis salar*).
2. Sea Carp (*Chilodactylus allporti*).
3. Black and Silver Perch (*Chilodactylus macropterus*).
4. Magpie Perch (*Chilodactylus gibbosus*).
5. Real Trumpeter (*Latris hecateia*).
6. Silver Bastard Trumpeter (*Latris forsteri*).
7. Rock Gurnet (*Sebastes percoides*).
8. Flathead (*Platycephalus bassensis*).
9. Tasmanian Whiting (*Sillago ciliata*).
10. Snotgall Trevally (*Neptonemus brama*).
11. Sea Mullet (*Agonostoma forsteri*).
12. Rock Cod (*Pseudophycis barbatus*).
13. Tasmanian Ling (*Genypterus blacodes*).
14. Flounder (*Rhombsolea monopus*).

In both the ponds and tanks of the Fisheries Establishment the chief attention is at present being given to the culture of oysters. There is already upon the premises a stock of some eight or ten thousand oysters of different varieties, and in all stages of growth, which stock it is proposed to yet further increase in anticipation of the approaching spatting-season. The varieties include the irregular-shaped Rock Oyster (*Ostrea angulata*) from New South Wales; the smooth variety of *O. edulis* from New Zealand, and many modifications of the indigenous type of the same species. The majority of these oysters have now been acclimatised in the tanks and ponds for the last three or four months, in which space of time it is gratifying to have to record that all of them have thriven and considerably increased the size of their shells. This is particularly noticeable of the New South Wales species, which it is anticipated from this experience it will be found possible to establish and propagate in these waters. The experiment now in course of trial, as to whether they will be able to withstand the severity of the Tasmanian winter months, will be an important factor in this question. The series under cultivation includes, in addition to the stock of adult oysters for breeding purposes, samples of brood raised last summer at Little Oyster Cove and other Government reserves. Among the useful functions accomplished by the Oyster-Culture Department of the Fisheries Establishment at Battery Point may be mentioned the *rôle* it fulfils of an accessible model for the advantage of those who, in increasing numbers, are taking up oyster-culture as a private enterprise, and who can there obtain information and instructions as to the best methods upon which to conduct their operations. It is also of much value as a central station, at which practical experiments can be made with the view of solving the many vexed problems that present themselves to the pioneers of this industry, and of discovering newer and more profitable methods of cultivating and breeding this mollusk. Already among eminent American and European oyster-culturists it is maintained that the secret of obtaining a far larger percentage of the brood produced by the parent oyster than has hitherto been accomplished is to be solved through the medium of tidal ponds and tanks, wherein the oysters will be supplied with all the equirements necessary for their healthy growth and development, and wherein at the same time suitable provision is made for the retention of the produced spat. Tentative experiments having this object in view are now in course of progress under scientific direction in all of the more important oyster-growing communities, and it is hopefully anticipated that some material assistance towards the solution of this important question may be forthcoming from this newly-established practical branch of the Fisheries Department of this colony.

Among the more important points to which my attention has been recently directed and advice solicited is the widely recognised desirability of discovering some method for cultivating oysters in localities in all respects suitable for their growth, with the exception that the labour involved in keeping them constantly clear from sedimentary deposits, or from sinking beneath a too yielding bottom, is too costly for their profitable culture. Experiments made with the view of surmounting this difficulty have resulted in the invention of a species of frame or cradle composed of wood and strong galvanised wire netting, measuring 6 feet long and 3 feet wide, upon which the oysters are placed, and raised to a height of from 9 to 10 inches off the ground. This description of frame so completely answers the purpose for which it was devised that they are being supplied to all of the Government reserves, and are recommended for the use of private growers. Each frame of the dimensions above quoted, which are found to be most portable, conveniently carries as many as 500 adult oysters, so that for a well-stocked bed of, say, 10,000 oysters, a score of them will be sufficient. Having the stock placed on frames of this description, a vast amount of labour usually bestowed in keeping the beds clean and the oysters free from sediment can be dispensed with. In place of the tedious process of dredging the bed through and raising the oysters a few at a time, to be cleaned and re-deposited on the cleared ground, each frame, with its contents, can be raised to the surface, a few shakes suffice to get rid of the sediment that may have accumulated upon them, and they may again be lowered to their place. This object may indeed be accomplished in many instances without raising the frames to the surface, it being sufficient merely to tilt the frame to and fro a few times, as it lies on the bottom, with the aid of a boat-hook, such agitations effectually getting rid of all the sedimentary matter. Wire handles for raising the frames to the surface of the water, with the aid of a boat-hook, should be attached.[1] Further advantages are attached to this frame-system of oyster-culture, since not only can the frames and their contents be raised to the surface at all times to be cleaned and manipulated, but it affords facilities, hitherto unprovided, of keeping an accurate estimate of the amount of stock placed upon the beds, and of watching, from time to time, the progress it is making in development. The form of spat collector that can be most advantageously utilised in conjunction with these oyster-frames is the one figured and described in my last Report under the title of the "single pale" collector, consisting, as its name implies, of a single split paling 4 feet long by 8 or 9 inches wide, having its under surface coated with cement and a brick attached at either end to retain it in the desired position. The experience gained by the past season has demonstrated this to be the most economic and productive form of collector, no alteration in its construction being suggested, with the exception that, by placing a single wire loop or handle in the centre instead of one at each end, as hitherto, their portability, both in and out of the water, is greatly increased. The adaptability of these paling collectors for use in conjunction with the newly-invented frames is very obvious, and their size is such as to allow of their being placed over the oysters in either a single or in two or more transverse rows. It is anticipated that the oysters placed upon the frames will of themselves constitute very efficient spat-collectors, their under surfaces, exposed through the meshes of the wire netting, being kept free from slime and sediment, and raised to a height above the ground favourable for the adherence of the spat. Empty shells or cultch similarly placed on frames in the vicinity of the breeding stock are also likely to prove favourable fulcra for the brood to adhere to. A remaining direction in which the oyster culture department of the Fisheries Establishment at Battery Point is found to be of great assistance in the operations now in course of progress relates to its value as a central depot for the reception and temporary storing of the stock brought from a distance for distribution among other reserves.

[1] The frames are raised to the surface of the water by blocks and cord attached to a tripod; where the boat is sufficiently large to carry a mast, the same apparatus may be more conveniently worked from a small derrick affixed to the mast.

THE FORMS OF SEEDLINGS: THE CAUSES TO WHICH THEY ARE DUE[1]

SIR JOHN LUBBOCK commenced the lecture with some general remarks on the innumerable types of foliage among mature plants and the causes to which we might refer their various forms, the breadth of some and narrowness of others, the differences of position, the differences of length in conifers, &c. He said that these considerations had led him to study the cotyledons or first leaves of seedlings. Cotyledons do not present such extreme differences as leaves; nevertheless, they afford a very wide range. Some are broad, some narrow, some are long, some short, some are stalked, some sessile, some lobed, some even bifid or trifid. At first sight these differences seem interminable, and it might appear hopeless to attempt to explain them. Sir John Lubbock, however, pointed out, as regards many species, taking especially the commonest plants, such as the familiar mustard and cress, the beech, sycamore, pink, chickweed, &c., the conditions of their formation and growth, and it is beautiful to see the various reasons to which the differences are due, gradually unfolding themselves; the same result being sometimes brought about by very different circumstances—emargination of the cotyledons, for instance, being due to at least six different causes. He mentioned one curious peculiarity in the seedling of a species allied to our common mistletoe. It is a parasitic species, and its fruit, like that of the mistletoe, is somewhat viscid, so that it adheres to any plant on which it falls. But, even if it reaches the plant on which it grows, it may light on an unsuitable position—say, for instance, a leaf. What then happens? The radicle elongates for about an inch, and then develops on its tip a flattened disk, which applies itself to the plant. If the situation be suitable, there it grows; if not, the radicle straightens itself, tears the berry from the spot where it is lying, curves itself, and then brings the berry down on to a new spot. The radicle then detaches itself, curves in its turn, and thus finds a new point of attachment. We are assured that this has been seen to happen several times in succession, and that the young plant thus seems enabled to select a suitable situation.

The form of the cotyledons, or seed-leaves, depends greatly on that of the seeds, long narrow seeds naturally, in most instances, producing embryos with narrow cotyledons. The cases, however, which can be so simply accounted for are comparatively few. Many plants with narrow cotyledons have flattened and orbicular seeds. In such species, however, the cotyledons lie transversely to the seed. An interesting case is afforded by the pink family, where the pink itself has broad cotyledons, while the chickweed has narrow ones. In both cases the seeds are flattened and orbicular, but in the pink the seed is dorsally compressed, and the cotyledons lie in the broad axis of the seed; while in the chickweed the seed is laterally flattened, and the cotyledons lie transversely to the seed.

Another very interesting case which he gave is that of the genus Galium, to which the common "cleavers" of our hedges belongs. Here also we find some species with narrow, some with broad, cotyledons; but the contrast seems to be due to a very different cause. *Galium aparine* has broad, *Galium saccharatum* narrow, cotyledons. So far as the form of the seed is concerned, there is no reason why the cotyledons should not be much broader than they are. The explanation may perhaps be found in the structure of the pericarp, which is thick, tough, and corky. It is very impervious to water, and may be advantageous to the embryo by resisting the attacks of drought and of insects, and perhaps even, if the seed be swallowed by a bird, by protecting it from being digested. It does not split open, and is too tough to be torn by the embryo. The cotyledons, therefore, if they had widened as they might otherwise have done, would have found it impossible to emerge from the seed. They evade the difficulty, however, by remaining narrow. On the other hand, in *Galium aparine* the pericarp is much thinner, and the embryo is able to tear it open. In this case, therefore, the cotyledons can safely widen without endangering their exit from the seed. The thick corky covering of *Galium saccharatum* is, doubtless, much more impervious to water than the comparatively thin test of *Galium aparine*. The latter species is a native of our own isles, while *Galium saccharatum* inhabits Algiers, the hotter parts of France, &c. May not then, perhaps, he suggested, the thick corky envelope be adapted to enable it to withstand the heat and drought. In this genus, as in many other plants, the embryo occupies only a part of the seed, being surrounded by a store of food or "perisperm." In many cases the embryo occupies the whole seed, and the cotyledons must, therefore, in large seeds, either be thrown into various folds, as in the beech, or be thick and fleshy, as in the bean or oak. The reasons for their numerous differences open up an inexhaustible variety of interesting questions. Sir John gave a great number of examples, which were rendered clearer by means of numerous diagrams of seeds and seedlings.

In conclusion, he said it might be asked whether the embryo conformed to the seed, or the seed to the embryo, and showed that, at least as regards certain species, the former was the case; while the shape of the seed, again, might be shown to be influenced by considerations connected with the construction of the fruit. In reply to this he compared the seedlings of the sycamore and of the oak. In the sycamore, the seed is more or less an oblate spheroid, and the cotyledons, which are long and ribbon-like, being rolled up into a ball, fit it closely, the inner cotyledon being generally somewhat shorter than the others. On the other hand, the nuts of the beech are triangular. An arrangement like that of the sycamore would therefore be utterly unsuitable, as it would necessarily leave great gaps. The cotyledons, however, are folded up somewhat like a fan, but with more complication, and in such a manner that they fit beautifully into the triangular nut. Can we, however, he said, carry the argument one stage further? Why should the seed of the sycamore be globular, and that of the beech triangular? Is it clear that the cotyledons are constituted so as to suit the seed? May it not be that it is the seed which is adapted to the cotyledons? In answer to this, we must examine the fruit, and we shall find that in both cases the cavity of the fruit is approximately spherical. That of the sycamore, however, is comparatively small, and contains one seed, which more or less exactly conforms to the cavity in which it lies. In the beech, on the contrary, the fruit is at least twice the diameter, and contains from two to four nuts, which consequently, in order to occupy the space, are compelled (to give a familiar illustration, like the pips of an orange) to take a more or less triangular form. Thus then, he said in conclusion, in these cases, starting with the form of the fruit, we see that it governs that of the seed, and that the seed again determines that of the cotyledons. But, though the cotyledons often follow the form of the seed, this is not invariably the case. Other circumstances, as I have attempted to show, must also be taken into consideration, and we can throw much light on the varied forms which seedlings assume.

I fear you may consider that I have occupied your time by a multiplicity of details, and I wish I could hope to have made those little plants half as interesting to you as they have made themselves to me; but, at any rate, I may plead that without minute, careful, and loving study, we cannot hope in science to arrive at a safe and satisfactory generalisation.

The lecture was accompanied not only by numerous diagrams, but by specimens, kindly lent by the authorities of Kew, and by some practical illustrations.

[1] Lecture at the Royal Institution, May 21, 1886, by Sir John Lubbock, Bart., M.P., D.C.L., LL.D., F.R.S., M.R.I.

ON THE USE AND EQUIPMENT OF ENGINEERING LABORATORIES

AT the ordinary meeting of the Institution of Civil Engineers, on Tuesday, December 21, 1886, Mr. Edward Woods, President, in the chair, the paper read was on "The Use and Equipment of Engineering Laboratories," by Prof. Alex. B. W. Kennedy, M.Inst.C.E. The author believed that it was essential for a young engineer to obtain his practical training, in the ordinary sense of the expression, in a workshop. But the practical training of a workshop was incomplete even on its own ground, and there appeared to be plenty of room for practical teaching such as might fairly fall within the scope of a scientific institution, and which should at the same time supplement and complete workshop experience without overlapping it. In an ordinary pupilage a young engineer did not have much opportunity of studying such things as the physical properties of the iron and steel with which he had to deal, nor the strength of those materials, nor the efficiency of the machines he used, nor the relative economy of the different types of engines, nor the evaporative power of boilers. He required such experience as might help him to determine for himself, or at least to see for himself how other people had determined, all the principal engineering constants, from the tenacity of wrought-iron to the calorific value of coal, or the efficiency of a steam-engine, or the accuracy of an indicator-spring, or the discharge-coefficient of an orifice. He thought that this kind of practical experience could be gained best in an Engineering Laboratory, in connection with some institution where technical instruction was given. He claimed that, in the matter of engineering laboratories, as a branch of technical education, England had really taken the lead, instead of being, as was too often the case in such matters, in the rear.

After distinguishing between laboratories whose chief function was original investigation or research, and those whose main object was the practical education of young engineers, and after giving an outline of the method of work which he had adopted, he went on to enumerate the principal subjects upon which experiments in an engineering laboratory might be carried out, summarising them thus:—(1) Elasticity and the strength of materials; (2) the economy, efficiency, and general working of prime movers, and especially of the steam-engine and boiler; (3) friction; (4) the accuracy of the apparatus commonly used for experimentation, such as springs, indicators, dynamometers, gauges of various kinds, &c.; (5) the discharge over weirs and through orifices, and hydraulic experiments in general; (6) the theory of structures; (7) the form and efficiency of cutting-tools; (8) the efficiency of machines, especially of machine-tools and of transmission-gearing; (9) the action and efficiency of pumps and valves; (10) the resistance of vessels and of propellers, and experiments in general connected with both. The paper dealt mainly with the three first subjects, the others receiving brief mention only.

In discussing the best form of testing-machine for laboratory purposes the author described specially the Werder machine, used by Bauschinger and largely elsewhere in engineering laboratories on the Continent, the vertical machine of Mr. J. H. Wicksteed, and the horizontal machine of Messrs. Greenwood and Batley, on Mr. Kirkaldy's principle, used by himself. Incidentally he described a number of other testing-machines, including the Emery machine at the United States Arsenal at Watertown, Fairbanks' machine, and others. The three machines first named were compared in some detail in respect to their accuracy, mode of applying load, methods of making observations, adaptability for varied experiments, simplicity, and accessibility, and the comparative advantages and disadvantages of each were discussed, the author preferring, on the whole, the Greenwood type. The method of testing employed by the author, with pump, accumulator, and Davy motor, was then described and illustrated,

Different apparatus for the measurement of minute extensions, compressions, &c., occurring below the limit of elasticity, were next discussed, the instruments specially mentioned being those of Prof. Unwin, Prof. Bauschinger, Mr. Stromeyer, and the author, as representing micrometric, optical, and mechanical exaggeration of strains. Automatic test-recording apparatus was next dealt with, Prof. Unwin's, Mr. Wicksteed's, Mr. Ashcroft's, and the author's diagramming machines being mentioned and illustrated. Automatic diagramming apparatus for elastic strains was next discussed. The paper contained *facsimiles* of various diagrams, both ordinary and elastic. In concluding this section of the paper, brief references were made to machines for transverse tests, torsional tests, shearing tests, cement and wire tests, secular experiments, experiments on repeated loads, &c.

In discussing the design of an experimental engine for laboratory purposes, the author first enumerated the principal conditions under which such an engine should be capable of working, summarising them thus:—(1) Condensing or non-condensing; (2) simple or compound; (3) compound, with cranks at various angles; (4) with the greatest possible variation of steam-pressure; (5) with the greatest possible variation of cut-off and other points in the steam distribution; (6) with the greatest possible variation of brake-power; (7) with considerable variation in speed; (8) with or without throttling; (9) with or without jackets, and with varying conditions as to their use; (10) with variation of clearance-spaces; (11) with variation of receiver-volume; (12) with or without arrangements for intermediate heating; (13) with variation in the reciprocating masses. He then enumerated the principal quantities which had to be measured during an engine-test, making remarks upon each important point in passing. A list was given of the principal experimental engines in existence, including those in London, Birmingham, Leeds, Munich, and Liége. This section was concluded by a description of the arrangement of an experimental boiler.

Under the head of friction-experiments, the principal points were summarised upon which experiments were required, in order that anything like a complete theory of friction in machines might be worked out. These included the variations of velocity, intensity of pressure, extent of contact, temperature, lubricant, method of lubrication, and nature of rubbing material. Friction-measuring machines, used or proposed by Prof. Thurston, Prof. R. H. Smith, Mr. Tower, and himself, were briefly described. The paper concluded with a few remarks on laboratory experiments connected with hydraulic work, the theory of structures, the form and efficiency of cutting-tools, the efficiency of machines and of transmissions, the action and efficiency of pumps and valves, and the resistance of vessels and propellers.

In an appendix there were added:—(*a*) Forms used by the author for conducting engine-trials. (*b*) Notes on the principal engineering laboratories in Europe and in America, with brief accounts of the chief apparatus used in each.

BIRDS' NESTS AND EGGS[1]

THE philosophy of birds' nests and eggs involves questions far too profound to be settled in an hour's lecture. The extreme partisans of one school regard birds as *organic automata*. They take a Calvinistic view of bird-life: they assume that the hedge-sparrow lays a blue egg because, under the stern law of protective selection, every hedge-sparrow's egg that was not blue was tried in the high court of Evolution, under the clause relative to the survival of the fittest, and condemned, a hungry magpie or crow being the executioner. The extreme partisans of the other school take an entirely opposite view. They regard the little hedge-sparrow, not only as a free agent, but as a highly intelligent one, who lays blue eggs because the inherited experience of many generations has convinced her that, everything considered, blue is the most suitable colour for eggs.

Perhaps the first generalisation that the egg-collector is likely to make is the fact that birds that breed in holes lay white eggs. The sand-martin and the kingfisher, which lay their eggs at the end of a long burrow in a bank, as well as the owl and the woodpecker, which breed in holes in trees, all lay white eggs. The fact of the eggs being white, and consequently very conspicuous, may have been the cause, the effect being that only those kingfishers which bred in holes survived in the struggle for existence against the marauding magpie. But the converse argument is equally intelligible. The fact that kingfishers breed in holes may have been the cause, and the whiteness of the eggs the effect; for why should Nature, who is generally so economical, waste her colouring-matter on an egg which, being incubated in the dark, can never be seen? The fact that many petrels and most puffins, which breed in holes, have traces of spots on their eggs, whilst their relations the auks and the gulls, who lay their eggs in open nests, nearly all lay highly-coloured eggs, suggests the theory that the former birds have comparatively recently adopted the habit of breeding in holes, and that consequently the colour being no longer of use is gradually fading away. Hence, we assume that the colour of the egg is probably the effect of the nature of the locality in which it is laid.

The second generalisation which the egg-collector is likely to make is the fact that so many of these birds which breed in holes are gorgeously coloured, such as kingfishers, parrots, bee-eaters, &c. The question naturally arises, Why is it so? The advocates of protective selection reply, Because their gay plumage made them so conspicuous as they sat upon their nests, that those that did not breed in holes became the victims of the devouring hawk, exactly as the conspicuous white eggs were eaten by the marauding magpie. But the advocates of sexual selection say that all birds are equally vain, and wear as fine clothes as Nature will let them, and that the kingfisher is able to dress as gorgeously as he does because he is prudent enough to breed in a hole safe from the prying eyes of the devouring hawk. The fact that many birds, such as the sand-martin and

[1] Abstract of a lecture delivered by Mr. H. Seebohm at the London Institution on December 20, 1886.

the dipper, which breed in holes, are not gorgeously coloured, while others, such as the pheasants and the humming-birds, are gorgeously coloured, but do not breed in holes, is evidence, as far as it goes, that the gorgeous colour of the bird is not the effect of its breeding in a hole, though the white colour of the egg probably is. It must be admitted, however, that the latter cases are not parallel. Whilst the hen kingfishers and bee-eaters are as gorgeous as their mates, the hen pheasants and the hen humming-birds are plainly, not to say shabbily, dressed. If birds be as vain as the advocates of sexual selection deem them, it must be a source of deep mortification to a hen humming-bird to have to pass through life as a foil to her rainbow-hued mate. Whilst the kingfisher relies for the safety of its eggs upon the concealed situation of its nest, the humming-bird depends upon the unobtrusiveness of the plumage of the sitting hen.

A very large number of birds, such as the grouse, the merlin, most gulls and terns, and all sandpipers and plovers rely for the safety of their eggs upon the similarity of their colour to the ground on which they are placed. It may be an open question whether these birds select a site for their breeding-ground to match the colour of the eggs, or whether they have gradually changed the colour of their eggs to match the ground on which they breed; but, in the absence of any evidence to the contrary, it is perhaps fair to assume, as in the previously mentioned cases, that the position of the nest is the cause, and the colour of the egg the effect.

Many birds make their nests in lofty trees, or on the ledges of precipitous cliffs. Of these, the eagles, vultures, and crows are conspicuous examples. They are, for the most part, too powerful to be afraid of the marauding magpie, and only fear the attacks of beasts of prey, amongst which they doubtless classify the human race. They rely for the safety of their eggs on the inaccessible positions of the nest. Many of them also belong to a still larger group of birds who rely for the safety of their eggs upon their own ability, either singly, in pairs, or in colonies, to defend them against all aggressors. Few colonies of birds are more interesting than those of herons, cormorants, and their respective allies. These birds lay white or nearly white eggs. Nature, with her customary thrift, has lavished no colour upon them because, apparently, it would have been wasted effort to do so; but the eggs of the guillemot are a remarkable exception to this rule. Few eggs are more gorgeously coloured, and no eggs exhibit such a variety of colour. It is impossible to suppose that protective selection can have produced colours so conspicuous on the white ledges of the chalk cliffs; and sexual selection must have been equally powerless. It would be too ludicrous a suggestion to suppose that a cock guillemot fell in love with a plain-coloured hen because he remembered that last season she laid a gay-coloured egg. It cannot be accident that causes the guillemot's eggs to be so handsome and so varied. In the case of birds breeding in holes secure from the prying eyes of the marauding magpie, no colour is wasted where it is not wanted.

The more deeply Nature is studied, the more certain seems to be the conclusion that all her endless variety is the result of evolution. It seems also to be more and more certain that natural selection is not the cause of evolution, but only its guide. Variation is the cause of evolution, but the cause of variation is *unknown*. It seems to be a mistake to call variation spontaneous, fortuitous, or accidental, than which expressions no adjectives less accurate or more misleading could be found. The Athenian philosophers displayed a less unscientific attitude of mind towards the Unknown when they built an altar in its honour.

SCIENTIFIC SERIALS

American Journal of Science, December 1886.—On the crystallisation of native copper, by Edward S. Dana. This elaborate memoir, which is illustrated with four plates figuring fifty-four varieties of native copper crystalline forms, is based chiefly on the fine collection of over sixty specimens from Lake Superior, belonging to Mr. Clarence S. Bement, of Philadelphia, supplemented by reference to the cabinets of Yale College Museum and Prof. G. J. Brush. The planes here determined are disposed in the three groups of tetrahexahedrons, trisoctahedrons, and hexoctahedrons, and include several new to the species. The paper also comprises an historical summary from the studies of Haüy and Mohs (1822) to the recent contributions of W. G. Brown.—On the trap and sandstone in the gorge of the Farmington River at Tariffville, Connecticut, by W. North Rice. The trap and sandstone of this locality are here specially studied with a view to the general elucidation of the history of these formations in the Connecticut Valley. The author's researches confirm the conclusion already arrived at by Prof. W. M. Davis, that some of the sheets of trap intercalated among the sandstones and associated rocks are contemporaneous, and others intrusive.—Comparative studies upon the glaciation of North America, Great Britain, and Ireland, by Prof. H. Carvill Lewis. This is an abstract of a paper by the author, read at the Birmingham meeting of the British Association last September. Its object is to show that the glacial deposits of the British Isles, like those of America, may be best interpreted by considering them with reference to a series of great *terminal moraines*, which both define confluent lobes of ice, and often mark the line separating the glaciated from the non-glaciated areas.—On certain fossiliferous limestones of Columbia County, New York, and their relation to the Hudson River shales and the Taconic system, by J. P. Bishop. The author describes some new fossils recently discovered in a metamorphic limestone occurring in the Chatham and Ghent districts on the western border of the Taconic slates of Columbia county, and tending to throw further light on the age of the Taconic formation. His investigations are still in progress, but from the facts so far determined, he considers that the fossils are of Trenton age, suggesting a synclinal having the Trenton limestone outcropping on both sides, and with the eastern edge pushed over westward.—Crystallised vanadinite from Arizona and New Mexico, by S. L. Penfield. The specimens here described and figured belong partly to the collection of the late Prof. B. Silliman, partly to that of Prof. Geo. J. Brush. Those from Pinal County, Arizona, are specially interesting, being of a deep red colour, and usually showing the very simple combinations already described by L. H. Blake.—The viscosity of steel and its relations to temper, by C. Barus and V. Strouhal. Having during the course of their former researches expressed the belief that the qualities of retaining magnetism exhibited by steel would probably stand in relation to the viscous properties of the metals, the authors here make a first search for such a relation. For several reasons their investigations are limited to torsional viscosity, and a new and very sensitive differential method is partially developed for the study of this property, with incidental reference to the viscosity of iron and glass. The results of the method as applied to steel are further compared with the known behaviour of permanent linear magnets tempered under like conditions.—Some remarks upon the journey of André Michaux to the high mountains of Carolina in December 1788, in a letter addressed to Prof. Asa Gray, by C. S. Sargent. Michaux's chief object was to secure living specimens of *Magnolia cordata*, and the locality explored by him appears to have been the highland region of North and South Carolina about the head waters of the Savannah River. The author has recently visited the same district for the purpose of re-discovering the same plant where Michaux was thought to have found it, but he searched for it in vain, and he concludes that Michaux's *Magnolia cordata*, as known in gardens, must be regarded as a rare and local variety of *M. acuminata*.—Note on the age of the Swedish Paradoxides beds, by S. W. Ford. It is argued on several grounds that these beds, or at any rate those above the division characterised by *Paradoxides kjerulfi*, are of the age of the Menevian group. Even this species should probably be referred to the same group, so that the strata containing it may be regarded as constituting a legitimate portion of the Swedish Paradoxides measures.

Rivista Scientifico-Industriale, November 1886.—On the development of atmospheric electricity which accompanies the condensation of aqueous vapour to rain or snow caused by a lowering of the temperature, by Prof. Luigi Palmieri. Those physicists who still doubt the reality of this phenomenon are recommended to conduct their researches with the Bohnenberger electroscope, as perfected by the author.—On the electric conductibility of vapours and gases, by Prof. Constantino Rovelli. Some experiments are described, fully confirming the important conclusions recently announced by Prof. Luvini regarding the non-conducting property of aqueous vapour.—On the pairing-season of frogs and toads in the Venetian district, by Dr. Alessandro P. Ninni. This period is shown to be determined by the atmospheric conditions, being advanced or retarded according to the mildness or severity of the weather in spring.

SOCIETIES AND ACADEMIES

London

Royal Society, November 18.—"On the Specific Heats of Minerals." By J. Joly, B.E., Trinity College, Dublin. Communicated by Prof. Fitzgerald, F.R.S.

A number of experiments—carried out by the method of condensation—are tabulated in this paper, on minerals whose specific heats have not previously been determined as well as on some mineral substances previously dealt with by Kopp, Regnault, &c.

The observation of specific heat is suggested as of value in determinative mineralogy. It is, with some exceptions, nearly constant for the same chemical composition, and calculable from an assumed chemical constitution, not alone in the case of simple compounds, but in the case, often, of the more complicated silicates, &c. No difficulty is introduced into its determination by conditions of aggregation such as looseness, &c. The method by weighing in air and steam admits of its value being very simply determined, and, if great accuracy be not required, very rapidly.

The experiments made by the writer show that there is a small variation in the specific heats of minerals of the same species, accompanying slight differences in translucency, lustre, perfection of crystalline form, the tendency being for the specific heat to be a minimum in the most perfect crystals. There is, further, in some cases, a variation of quite different order accompanying pronounced differences in physical appearance, as from the transparent aquamarine to the clouded beryl, sapphire to corundum, &c.; so that a distinct and definite value exists for each variety, unaccounted for by any probable variation in chemical composition.

It appears, also, that this kind of variation obtains in the case of the isometric sulphides, pyrite, galenite, sphalerite, and in such degrees as admit of the several values being stated in numerical proportion from one substance to another. Thus, using the initial letters for the observed values, it is found that—

$$p_1 : p_2 :: g_1 : g_2;$$

and, if the orthorhombic disulphide of iron, marcasite, be included, the proportion

$$s_1 : s_2 :: p_1 : m :: g_1 : g_3$$

obtains very closely. The observations of other observers are included in these ratios, the existence of which, if further borne out, suggest as an explanation the existence of variations of structure of definite character affecting, in a definite way, the freedom of the atom. From this point of view, the case of marcasite would be that in which such variation proved adequate to determine a special symmetry for the aggregate.

December 9.—"Note to a Paper on the Geometrical Construction of the Cell of the Honey-Bee" (*Proc. R.S.*, No. 240, p. 253, 1886). By Prof. H. Hennessy.

The author found in the foregoing paper that a side of one of the lozenges terminating the cell was three times the difference between two parallel edges of the hexagonal prism, and from this result he constructed one of the lozenges by erecting a perpendicular at one-third of its length from one end, and from this end, with radius equal to the side, he inflected a second side of the lozenge, which gave the whole figure and also the six trapeziums forming the prism. With a compass and ruler the whole figure can be thus easily constructed.

The author further proves that the triangular pyramid which terminates the bee's cell may be inscribed in a sphere whose diameter is three times one of the edges of the pyramid. Moreover, this sphere contains within it as much of the hexagonal prism as may be measured by twice the side of a lozenge on the prism's shorter edge. These results, together with the extremely simple mode given by the author for constructing the figure, divest the problem of the complex character which it was sometimes supposed to have, and they may also assist in explaining the action of the bees in moulding the cells of the honeycomb to their observed shapes.

"The Intra-ovarian Egg of some Osseous Fishes." By Robert Scharff, Ph.D., B.Sc. Communicated by Prof. McIntosh, F.R.S.

December 16.—"On the Changes in the Proteids in the Seed which accompany Germination." By J. R. Green.

The author described experiments proving the existence in germinating seeds of a ferment resembling the proteolytic ferment of the pancreas. This exists in the resting seeds in the condition of a mesostate or zymogen, and is, on the starting of the germinative process, transformed into the active ferment. He traced the changes which it brings about in the reserve proteids of the seed, and showed that, while they passed through the stage of peptone, the nitrogen was carried to the growing points in the condition of a crystalline amide, such as leucin, asparagin, &c.

Zoological Society, December 21, 1886.—Prof. W. H. Flower, LL.D., F.R.S., President, in the chair.—Mr. Howard Saunders, F.Z.S., exhibited and made remarks on a specimen of a hybrid between the Tufted Duck and the Pochard, bred in Lancashire in 1886.—Mr. J. Bland Sutton, F.Z.S., read a paper on atavism, being a critical and analytical study on this subject.—Dr. von Lendenfeld read a paper on the classification and systematic position of the Sponges. This was based on the recent researches on the Hexactinellida, Tetractinellida, and Monaxonida of the *Challenger* Expedition, and on his own investigations on the rich Australian Sponge-fauna, particularly of the groups Calcarea, Chalinidæ, and Horny Sponges. A complete system of Sponges was proposed, and worked out down to the families and sub-families, and all the principal genera were mentioned. An approximately complete list of the literature of Sponges (comprising the titles of 1446 papers), a "key" to the determination of the 46 families, and a discussion of the systematic position of the Sponges were also contained in the paper.—Prof. Ray Lankester communicated a paper by Dr. A. Gibbs Bourne, of the Presidency College, Madras, on Indian earthworms, containing an account of the earthworms collected and observed by the author during excursions to the Nilgiris and Shevaroy Hills. Upwards of twenty new species were described.

Geological Society, December 15, 1886.—Prof. J. W. Judd, F.R.S., President, in the chair.—John Usher and Joseph Tertius Wood were elected Fellows of the Society.—The following communications were read:—Notes on *Nummulites elegans*, Sow., and other English Nummulites, by Prof. T. Rupert Jones, F.R.S. The author finds, in the "Sowerby Collection," now in the British Museum, the original specimens on which Sowerby founded his *Nummularia elegans* (1826, "Min. Conch." vol. vi. p. 76). These are partly specimens from that part of the bed "No. 29" of Prof. Prestwich's section of Alum Bay (Quart. Journ. Geol. Soc., vol. ii. (1846), p. 257, pl. ix. fig. 1), which is known to be the lowest of the Barton series; and partly some in a stone said to be from Emsworth, in Hampshire. The former are the same as those named *Nummulites planulata*, var. *Prestwichiana*, by Rupert Jones in 1852; and the latter are *N. planulata*, Lamarck (1804), and probably foreign. Thus *N. elegans* has priority over *Prestwichiana*; and as this last was determined by De la Harpe to be a variety of *N. wemmelensis*, Van den Broeck and De la Harpe, this variety should be var. *elegans*. The author thinks that, on broad zoological principles, *N. planulata* might still be regarded as the species; but, in view of the careful differentiation worked out by De la Harpe, he accepts the "specific" standing of "*wemmelensis*" as useful among *Nummulites*; but "*Prestwichiana*" has to give way to "*elegans*" for the peculiar "Barton" variety. A bibliographical history of the long-misunderstood *N. elegans*, Sowerby, descriptions of this form and of *N. variolaria* (Lam.), notes on *N. lævigata* (Brug.), and an acccount of their range in England, complete the paper.—On the dentition and affinities of the Selachian genus *Ptychodus*, Agassiz, by A. Smith Woodward, F.G.S. The genus *Ptychodus*, owing to the detached condition in which the teeth are usually found, has hitherto been imperfectly understood. Agassiz referred it to the Cestraciontidæ, on account of a supposed resemblance in the arrangement of the teeth, and Owen's researches on their microscopic structure served to confirm this view. On the other hand, several writers have pointed out characters tending to show affinity between *Ptychodus* and *Rhynchobatus*. More recently, however, Prof. Cope and the author had shown that the supposed affinities between *Ptychodus* and the Cestraciontidæ were only apparent, and in the present paper additional evidence was brought forward. The author proceeded to describe several specimens of *P. decurrens* in the British Museum, and in the collection of Mr. H. Willett, of Brighton, one of the latter, especially, containing, what had been previously entirely unknown, the dentition in part of both jaws. These specimens showed that each jaw contained six or seven longitudinal rows of teeth on each side of the median row, and that the genus must be referred to the true Rays, and not to the Cestraciont sharks, though the precise family to which *Ptychodus* belongs was more difficult to determine. On the whole the writer was disposed to assign it a place either amongst the Myliobatidæ or in their neighbourhood. The microscopic structure of the teeth was shown to be insufficient, by itself, to show their affinities.—On a molar of a Pliocene type of *Equus*, from Nubia, by R. Lydekker, B.A., F.G.S. A small collection of Mammalian remains from near Wadi Halfa had recently been placed in the author's hands; some of the bones were mineralised similarly to those of the Upper Pliocene of the Val d'Arno, or the Lower Pleistocene of the Narbadda valley. Amongst others, the most interesting is a right upper cheek-tooth of *Equus* but little worn. It evidently does not belong to any of the late Pleistocene or recent species of the genus, but to the more generalised group comprising *E. sivalensis*, &c.; though, bearing in mind the impossibility of distinguishing many of the existing species of the genus by their teeth alone, its absolute specific identity is not asserted. We may infer, then, that the ossiferous beds of Wadi Halfa are not improbably of Pliocene age, since this group of horses, both in Europe, Algeria, and India, had totally disappeared after the period of the forest-bed. Moreover, it is of interest, in view of previously expressed opinion, to find in the Tertiary of Nubia a species of this primitive group of *Equus*, which is apparently more nearly allied to the Siwalik than to the European species.

Royal Microscopical Society, December 8, 1886.—Rev. Dr. Dallinger, F.R.S., President, in the chair.—Mr. J. Mayall, Jun., called attention to a microscope, exhibited and made by Mr. Hilger after the designs of Sir A. Campbell, for measuring with great accuracy the divisions ruled upon a diffraction-plate. A special feature was the application of electricity, so that, by means of a weak battery and a galvanometer, it could be arranged that a contact should be made when passing every line, such contact being shown instantly by a deflection of the galvanometer-needle. In this way, end-measurements could be made with great accuracy.—Mr. Mayall also exhibited and described a new form of heliostat (made by Mr. Hilger) for use in solar photomicrography. The pencil of sunlight reflected from the first mirror could, by means of the second, be directed in any desired direction, affording to the worker the very great advantage of being able to place his microscope and camera in any position he pleased.—Mr. F. R. Cheshire exhibited and described an improved form of inoculating needle for use in connection with Bacterium culture-tubes. It was mounted in a wooden handle having a square ferrule which prevented it from rolling when placed upon an unlevel surface; in this was inserted a piece of silver tube, at the end of which was the platinum wire. A circular disk of silver was fixed on the tube, which, when placed in the flame of a lamp, rapidly became hot, and communicated the heat to the needle, while the small size of the tube enabled it to be introduced into the culture-tube more easily than the glass rod usually employed.—Prof. Bell called attention to some specimens exhibited of *Tænia nana*, the smallest of the human tape-worms, originally found by Bilharz in Egypt in 1850. Though extremely rare, it had the great advantage, to the physiologist at least (though not perhaps to the patient), of being found in considerable numbers. In the present instance the worms had been found in quantities in the duodenum of a girl aged seven years, at Bellegarde. The largest specimen met with was only 15 millimetres long.—Mr. J. D. Hardy called attention to a paper, by Dr. O. Zacharias, in which it was stated that Rotifers could never be revived after desiccation. He thought a protest should be entered against this, as it was within his knowledge that revivification had taken place over and over again. He had frequently tried the experiment, and had found that, when the dried mud was moistened, the Rotifers constantly revived. Prof. Stewart pointed out that a good deal must turn on what was meant by "desiccation." It was exceedingly difficult, under ordinary circumstances, to produce a condition of complete desiccation, and it was therefore very probable that in all cases of revivification there was sufficient moisture retained to preserve life. Prof. Bell said this explanation had usually been accepted as the real one when this subject perennially came to the front. The most curious part of Dr. Zacharias's paper, however, was that he did not in any way attempt to criticise the observations of his predecessors on the facts, but simply declared them to be fables, not inquiring at all into the conditions under which the revivals took place, so as to ascertain whether or not they were desiccated in the same sense in which his objects were when dried up in a granite basin. A discussion ensued, in which the President, Mr. Crisp, Mr. Michael, and Mr. Lewis joined.—Colonel O'Hara's note on the dissimilarity of appearances of crystals of blood as examined by him, and the illustrations in text-books, was read.—Mr. P. H. Gosse's paper, on twenty-four new species of Rotifera, was read, and two plates, drawn by Mr. Gosse in illustration, were handed round for inspection.

Anthropological Institute, December 14.—Francis Galton, F.R.S., President, in the chair.—The election of Mr. J. A. Otonba Payne, of Lagos, as an Ordinary Member, and of Dr. W. J. Hoffmann as a Corresponding Member, was announced. —Dr. E. B. Tylor read a paper by the Rev. G. Brown on Papuans and Polynesians, in which Mr. Brown contended that, notwithstanding physical differences, the similarity of their languages and customs prove the Papuans and the inhabitants of all the Pacific Islands have a common origin.—The following papers were also read:—Notes on songs and song-makers of some Australian tribes, by A. W. Howitt, F.G.S.—Music of the Australian aborigines, by G. W. Torrance, Mus.D.—On the aborigines of Western Australia, by R. H. Bland.

PARIS

Academy of Sciences, December 27, 1886.—M. Jurien de la Gravière, President, in the chair.—The proceedings were opened with an eloquent allocution by the President on the progress and triumphs of science during the past year, with a touching allusion to the loss sustained by the Academy in the death of its distinguished members, MM. Tulasne, de Saint-Venant, Laguerre, and Paul Bert.—The allocution was followed by the announcement of the prizes awarded during the year to the successful competitors in the various branches of the physical and natural sciences:—Prix du Budget (Mathematics), Édouard Goursat; Prix Francœur (Geometry), Emile Barbier; Extraordinary Prize of 6000 francs (Navigation), Capt. G. Fleuriais 4000 francs, Capt. de Bernardières 2000 francs; Prix Montyon, 2500 francs (Mechanics), M. Rozé; Prix Plumey (Naval Engineering), M. de Bussy; Prix Poncelet (Mathematics), Emile Picard; Prix Lalande (Astronomy), M. O. Backlund; Prix Damoiseau (Astronomy), M. Souillart, and to M. Obrecht 1000 francs; Prix Valz (Astronomy), M. Bigourdan; Prix Bordin (Optics), M. R. Radau; Prix Montyon (Vital and Social Statistics), M. Victor Turquan, with honourable mention of Dr. Mireur, Cazin, and Socquet; Prix Jecker (Chemistry), divided equally between MM. Colson and Oechsner de Coninck; Prix Vaillant (Geology), the members of the French Mission to Andalusia, MM. Michel Lévy, Bertrand, Barrois, Offret, Kilian, and Bergeron, and 1000 francs to M. de Montesson; Prix Barbier (Botany), M. Eugène Collin; Prix Desmazières (Botany), MM. H. van Heurck and A. Grunow; Prix de la Fons Mélicocq (Botany), divided equally between MM. Gaston Bonnier, G. de Layens, and E. G. Camus; Prix Montagne (Botany), Dr. Quélet; Prix Thore (Entomology), M. Peragallo; Prix Montyon (Medicine), Drs. Léon Colin, Dejerine and Landouzy, and Oré, 2500 francs each, besides honourable mention with 1500 francs to MM. Cadéac and Malet, Masse, and Ollivier; Prix Bréant (Medicine), Dr. Duflocq 2000 francs, M. Ad. Guérard 1500 francs, and M. Thoinot 1500 francs; Prix Godard (Surgery), M. Bazy; Prix Lallemand (Surgery), M. W. Vignal; Prix Montyon (Experimental Physiology), M. Gréhant, with honourable mention of M. Assaky; Prix Gay (Physical Geography), M. Ph. Hatt; Prix Montyon (Unhealthy Industries), MM. Appert Brothers, and M. Kolb 2500 francs; Prix Trémont (Magnetism), M. Moureaux; Prix Gegner, M. Valson; Prix Delalande-Guérineau (Terrestrial Physics), M. Hyades; Prix Jean Reynaud (Therapeutics), M. Pasteur; Prix Ponti (Aërial Navigation), MM. Renard and Krebs; Prix Marquise de Laplace, M. E. A. Brisse.—Prizes proposed for the year 1887:—Francœur, 1000 francs, discoveries or works useful to the progress of pure and applied mathematics; Extraordinary Prize of 6000 francs, works tending to increase the efficiency of the French naval forces; Poncelet, 2000 francs, for the most useful work for the advancement of the pure and applied mathematical sciences; Montyon, 700 francs, mechanics; Plumey, 2500 francs, improvement of steam-engines, or any other invention contributing most to the progress of steam navigation; Fourneyron, 500 francs, theoretical and practical study of the progress made in aërial navigation since 1880; Lalande, 540 francs, Valz, 460 francs, and Damoiseau and Janssen, gold medals, works contributing to the advancement of astronomy; Grand Prize of the

Mathematical Sciences, 3000 francs, researches on the elasticity of one or more crystallised bodies from the experimental and theoretical standpoints; L. Lacaze, 10,000 francs each, to the authors of the best work on physics, chemistry, and physiology; Montyon, 500 francs, vital statistics; Jecker, 10,000 francs, organic chemistry; Delesse, 1400 francs, to the author of a treatise on the geological or mineralogical sciences; Barbier, 2000 francs, for any valuable discovery in surgery, medicine, pharmaceutics, or botany, in connection with therapeutics; Desmazières, 1600 francs, for the most useful work on the whole or any section of cryptogamy; Thore, 200 francs, awarded alternately for works on the cellular cryptogams of Europe, and for researches on the habits and anatomy of any European entomological species; Montagne, 1000 and 500 francs, to the authors of important works on anatomy, physiology, the development or description of the lower cryptogams; Grand Prize of the Physical Sciences, 3000 francs, researches on the phenomena of phosphorescence in animals; Bordin, 3000 francs, for a comparative study of the African, South Asiatic, and Australasian freshwater fauna; Bordin, 3000 francs, for a comparative study of the auditory apparatus in the warm-blooded vertebrates, mammals, and birds; Savigny, 975 francs, for young zoological travellers; Montyon, 750 francs, medicine and surgery; Bréant, 100,000 francs, to the discoverer of an efficacious remedy against Asiatic cholera; Godard, 1000 francs, anatomy, physiology, and pathology of the genito-urinary organs; Serres, 7500 francs, general embryology, especially as applied to physiology and medicine; Chaussier, 2500 francs, for important works on forensic and practical medicine; Lallemand, 1800 francs, for works relating to the nervous system in the widest sense of the term; Montyon, 750 francs, experimental physiology; Gay, 2500 francs, distribution of heat on the surface of the globe; Montyon, unhealthy industries; Trémont, 1100 francs, for any naturalist, physicist, artist, or mechanician needing assistance in the accomplishment of any undertaking useful to France; Gegner, 4000 francs, in aid of any *savant* distinguished by serious pursuits undertaken for the purpose of advancing the positive sciences; Petit D'Ormoy, 10,000 francs, pure and applied mathematics, and the natural sciences; Laplace, a complete edition of the works of Laplace, for the first student leaving the Ecole Polytechnique. General conditions: the Academy retains all memoirs, the authors being at liberty to obtain copies from the Secretary. Competitors must send in their papers by June 1, accompanied by a brief summary of the part containing the discovery on which they desire the judgment of the Academy. No one can claim the title of Laureate of the Academy unless awarded a prize. Honourable mention or any other formal recognition of merit does not justify the assumption of this title.

STOCKHOLM

Society of Natural Science, September 18.—Prof. Wittrock gave an account of the gypsies, chiefly in relation to Hungary, which country he had recently visited with a view to studying its various nationalities.—Dr. Skåuberg exhibited abnormal specimens of various plants he had found in Sweden last summer, viz. *Phleum pratense*, *Listera ovata*, *Linaria cymbalaria*, *Typha angustifolia*, and *T. latifolia*.—Herr Berggren exhibited a specimen, in spirits, of *Nyctalis parasitica*, which had grown on another fungus, *Russula adusta*, whilst the latter was still quite fresh. The former fungus, he said, was also at times attacked by a smaller parasitic one, imparting to it a kind of coating.—Herr Meves exhibited a specimen of *Oriolus gulbula*, shot last May, a bird very rarely found in Sweden.

Entomological Society, September 25.—Prof. Chr. Aurivillius gave an interesting account of his studies, last summer, of the habits of various species of Hymenoptera. He specially referred to one, *Odynerus muralis*, which he had found when boring holes in red-painted wooden walls, at the bottom of which it deposited its larvæ, protecting the latter against attack by making partitions of clay at intervals, and by putting a prop at the end, which it carefully covered with tiny bits of red paint, whereby these holes were almost impossible to detect.—Dr. Lampa described his observations of the remarkable keenness of the olfactory organs of the males of *Bombyx quercus*, L., whereby they were enabled to discern the females, even when far off. In one instance a female had been discovered by a male, although access to the former, which was in a cage, could only be gained through a balcony and room beyond.—Dr. Adlerz referred to an unusual case of hermaphroditism in an ant, whose left half was formed like a male, and the right like a female.

CHRISTIANIA

Society of Sciences, October 1.—The following papers were presented:—Der Ursprung der Etrusker durch zwei lemnische Inschriften erläutert, by Prof. Sophus Bugge.—Fresh contributions to our knowledge of the extension of the tube plants in Norway, by Prof. A. Blytt.—On variations in climate in the course of time (see NATURE, vol. xxxiv. pp. 220 and 239), by the same.—Ueber die Entwickelungsgeschichte der Pollenkörner des Angiospermen, by Dr. N. Wille.—Fresh contributions to our knowledge of the extension of lichen in Norway, by Herr B. Kaalaas.—Dr. G. Storm read a paper on voyages to countries north and north-west of Iceland, maintaining that the priests who, in 1285, discovered "Nya Land" (New Land) did not reach Newfoundland, but the south-eastern part of Greenland, and that the island discovered in 1194, "Svalbarde," was Jan Mayen. He further believed that the old Norsemen knew of other Arctic countries north of Russia and Norway.

BOOKS AND PAMPHLETS RECEIVED

Annual Report of the Geological and Natural History Survey of Canada, new series, vol. i.: A. R. C. Selwyn (Dawson Bros., Montreal).—Negretti and Zambra's Encyclopædic Catalogue.—Proceedings of the Royal Physical Society, Session 1885-86 (M'Farlane and Erskine, Edinburgh).—Den Norske Nordhaus-Expedition, 1876-78, XVI. Zoologi, Mollusca, II.: H. Friele (Grondahl, Christiania).—Transactions of the Sanitary Institute of Great Britain, vol. vii. 1885-86 (Stanford).—Zeitschrift für Wissenschaftliche Zoologie, xliv. Band, 4 Heft (Engelman, Leipzig).—Geological Survey of Alabama—On the Warrior Coal-Field: H. McCalley (Montgomery).—Year-book of Photography, 1887 (Piper and Carter).—Anuario de la Oficina Central Meteorolojica de Chile, 3er Cuaderno, Mayo i Junio.—Fourth Annual Report of the Metropolitan Public Gardens Association.

THURSDAY, JANUARY 13, 1887

SCIENCE AND THE JUBILEE

II.

IN our article last week we referred to two directions in which the Jubilee memorial could in our opinion be made to fulfil functions of the highest importance which none of our existing institutions could take up, and we pointed out that one of them would be almost exclusively scientific.

The fact that so distinguished a man of science as Sir Frederick Abel has been appointed the organising secretary of the new institution amounts almost to an assurance that these possible high purposes will not be lost sight of. Sir Frederick Abel has proved himself to be not only a brilliant and patient investigator of new problems in science, but also one of those men whose indomitable energy and administrative power peculiarly fit him for a post in which sympathy with science in its highest aspects must be associated with a keen knowledge of and interest in affairs.

It is not merely a coincidence, but rather a sign of the times, that this week we refer in our columns to two other apparently distinct subjects, which in fact are most germane to the one we are discussing. The first is an article by Mr. Morris on the botanical federation of the West Indies, and the second is the recently issued Report of the Committee appointed by the Government to consider the question of the national science collections. Mr. Morris's article is connected with the proposed Jubilee memorial in this way: it shows that already, by the nature of things, the West India Islands are associating themselves with the mother country in things botanical, as, according to our view, all our colonies should in things scientific generally. The necessity, the thoroughness, and the economy which obviously must result from such an arrangement are well stated by Mr. Morris, than whom we know no higher authority. It should be a subject of pride to our men of science that, thanks to the broad views taken by three successive Directors of the Royal Gardens, Science is ahead of politics on a line where politics is bound to follow her; for the political federation of the West India Islands is a thing of the not very distant future. This reference to the West Indies induces us, almost compels us, to return for one moment to another matter touched on in our article last week. We then pointed out that topography, geology, and botany would not be the only arts of peace to which we need confine ourselves. Now, we are inclined to believe that any money which might be spent in federating the West Indies meteorologically by means of the telegraph, even if new cables had to be laid here and there, would be saved over and over again in twenty years by the protection afforded to shipping by forecasts during the hurricane season. Now, supposing such a system as this at work in one of the most interesting regions of the world from a meteorological point of view, and controlled, if need be, from the mother country, represented by the Meteorological Council, good would come all round; the Meteorological Council would gain a larger and closer view of the phenomena which it is its duty to study, and the federated colonies would obviously gain by the reduction in the yearly loss of life and capital.

We now pass to the Report on the National Science Collections. The connection between this Report and the proposal for the Institute can be gathered from the following statements.

We showed in our last article that the Committee appointed by the Prince of Wales were driven to South Kensington for a site by stress of money, even supposing that South Kensington was the worst possible site that could be selected. Our opinion is that South Kensington is the best site that could be selected for any institution which is to be anything more than an expanded Chamber of Commerce or Mart. But, however this may be, the fact remains that the Institute buildings, if erected at all, will be erected at South Kensington. Further the building must have a frontage.

It will be gathered from the Report of the Government Committee on the Science Collections that it is proposed to house them, including the historical and other objects recently transferred from the Patent Museum, in a building to run from Prince's Gate to Queen's Gate, at the back of the Museum of Natural History. Now, why should not the Royal Commissioners and the Government arrange matters so as to enable the Science Museum, which thus must be geographically associated with the Institute, to be commenced at the same time? In this way, it appears to us that the Royal Commissioners would have fully discharged their functions as regards the southern part of the land for which they are trustees, provided always that the Institute is really to promote the progress of science and art.

One word now as to the real place of this Science Museum among our national institutions for the promotion of knowledge. The student of literature in this country—the man who has to make new books, or whose desire it is to obtain any of the knowledge contained in old ones—finds in the British Museum library and reading-room the most magnificent organisation to supply him with what he wants. In this respect the British citizen to-day is as well off as, but perhaps no better off than, the citizen of Alexandria was in olden times; and now, as then, it is conceded that it is the duty and glory of a State which makes any pretence to civilisation to have such an institution as this among its resources. It is one of the arsenals of peace.

Turn to another line of intellectual activity: take the student of the biological sciences. The British Museum of Natural History is a library no longer containing books merely, but things which have to be studied to obtain new knowledge. Here, as among the books, the student is allowed to examine, to study, to collate, and to describe without stint, microscopes and other apparatus being provided for him; facilities are afforded to him in order that he may learn, and that the field of knowledge may be enlarged through his labours.

Yet another region of activity: take Art in all its branches. Our National Gallery and the art collections at the British Museum and South Kensington show that in past times, at all events, the State has considered it its duty to bring together collections for the benefit of the student, and even for the delight of the eye of the uninformed.

These institutions are not merely depositories for loans, in which the State enables its citizens to be benefited provided only that the process costs nothing, or next to nothing; but fabulous sums have at times been given, and willingly given, by the nation in order that we shall not be behind others in the opportunities afforded of cultivating the arts of peace.

We now come to the newest developments of human activity. We leave the ground common to us and Greece and Rome, and we approach the modern world, the world which is as it is because physics and mechanics and chemistry have been developed since those earlier days to which we have referred. These developments form the glory of our modern civilisation, and are the pith and marrow of our national life.

What do we find in our national collections representing these in this our England, where till a few years ago physics, mechanics, and chemistry had been most, and most successfully, applied?

Nothing, or practically nothing. The State, which has absorbed greedily some two millions nett in patent fees which have come into its coffers in consequence of these developments, has given nothing, or practically nothing, back. It is true that the generosity of private individuals has enabled the nation to possess and exhibit some of the most interesting among the historical apparatus illustrating the applications of those branches of science to which we refer. It is true also that the Science and Art Department has done its best to make bricks without straw, and the state of things is better now than it was ten years ago. We say ten years ago, because it is about that period since the Duke of Devonshire's Commission pointed out in the clearest and most emphatic way this great and damaging gap in our national resources, and pointed out, too, the various evils which would arise from it. Since that time other Committees have reinforced the Commission's suggestions. Those who know best know how well for the country it would be if the modern developments of knowledge were illustrated as well as the older ones. It is true that after ten years the thing has gone so far that a Treasury Committee has been appointed to consider how such a national collection could be housed. But it is not impossible that another ten years may elapse before anything is done, unless some special and extraneous reason be urged for the doing of it.

Then why should not the men of science in this year of Jubilee urge upon the Government that it also should not be lacking in commemorating this year? If the citizens of Greater Britain contribute a quarter or half a million in commemorating the year, why should not the Government contribute some 25,000*l.* (as an instalment of 100,000*l.*, which is all such a Museum need cost) in starting an institution which all students of science or its applications know will be the most important of all in fifty years time, most important, that is, in everything that relates to the development of the resources of Greater Britain?

So much then for what the Government might well do in the year of Jubilee. It remains for us to consider what men of science as such can do. We believe that the keynote of what they can best do was struck by Prof. Huxley as President of the Royal Society. To this matter we shall probably take another opportunity of referring.

MARINE ENGINEERING

Die Schiffsmaschine; ihre Construction Wirkungsweise und Bedienung. Bearbeitet von Carl Busley. (Kiel: Verlag von Lipsius und Tischer, 1886.)

THE concluding volume of this important work on marine engineering equals in merit and style the portion previously published, of which a notice appeared in NATURE, vol. xxix. p. 426. It is a most laborious and well-digested compilation of all that is best worth preserving in relation to the resistance and propulsion of ships. The author with true German industry has sought far and wide for his materials, drawing from the writings of French, German, Dutch, American, and English authorities. But it may be stated with some satisfaction that the most recent and valuable investigations to which reference is made are those of our own countrymen. The labours of the late Mr. Scott Russell, Prof. Rankine, and Mr. W. E. Froude, have given an impulse and direction to the theoretical and experimental investigations of the problems of resistance and propulsion, of which the practical value cannot well be over-estimated. The action of the Admiralty in assisting the late Mr. Froude, and in now establishing, under the able direction of Mr. R. E. Froude, experimental works on an enlarged and permanent basis, has yielded substantial advantages to the Royal Navy, and benefited the science and practice of shipbuilding generally. One private firm on the Clyde has, for its own purposes, created a similar experimental establishment; another was established in Holland by the late Chief Constructor, Dr. Tideman; France has done something in the same direction; and Russia and the United States have given attention to the matter. Everywhere it is now recognised that the resistances of full-sized ships may be closely approximated to by means of experiments with models; and in this manner the problems of ever-increasing difficulty incidental to the attainment of higher and yet higher speeds are being dealt with confidently and successfully. Pure theory cannot master these problems, although it has suggested the best experimental procedure. The older theories of resistance summarised by Mr. Busley have given place to the "stream-line" theory, and upon it has been based the "law of comparison" between ships and models independently laid down by the great French teacher, M. Reech, and the late Mr. W. Froude.

Mr. Busley shows full appreciation of the value of these modern experimental methods, while he also describes the more or less "rule-of-thumb" methods which formerly prevailed and have still their uses. It is not possible for most shipbuilders and marine engineers to have model experiments for new ships, and they therefore depend largely upon the analysis of the results of speed trials made with other ships. Carefully conducted trials on what is called the "progressive" principle—that is, at a number of different speeds from the maximum speed attainable down to four or five knots per hour—are of the greatest value to future designs of ships and machinery. For a long time they have been made occasionally in the Admiralty practice; but Mr. W. Denny deserves great credit for bringing the system into general use and establishing its practical value. Associating progressive trials with the "law of comparison" for the resistances of ships of different dimensions but similar forms, a designer can feel great confidence of success in most of his practice. If he has the *data* for small ships propelled at relatively high speeds, he has the means of approximating closely to the performances of larger ships up to much higher speeds, and this is of enormous value under present conditions.

Methods of *propulsion* and details of *propellers* occupy a large section of the volume under review. The paddle-wheel, the screw, and the water-jet propeller all receive full discussion in their theoretical and practical aspects. Probably no such summary of facts relating to modern practice has been made before by any writer. Under paddle-wheels, for example, there are descriptions constituting practical data for designing paddles at the *sides* of steamers (the ordinary plan), at the *stern*, as in light-draught river-steamers, and at the *centre*, between twin hulls, as is the fashion in some American river-steamers. Under the jet-propeller appears a great mass of information as to the fittings and performances of a number of vessels, including the English gunboat *Waterwitch* and Thornycroft's torpedo-boat of recent construction, the German *Hydromotor*, described in NATURE, vol. xxvi. pp. 18 and 247, and a Swedish experimental boat. Naturally the greatest attention is bestowed upon screw-propellers, which are most generally employed. To the theory of the screw-propeller laid down by Rankine, many valuable additions have been made by the Froudes, father and son, Mr. R. Froude being still engaged in the investigation of the subject experimentally. Up to the present, however, it cannot be said that any complete, acceptable theory has been put forward. Experience shows that by the choice of proper screws enormous economies of power or sensible increases in speed may be secured. The first trials of H.M.S. *Iris*, nearly ten years ago, were fortunately most disappointing, for they compelled a close study of the screw question in her case, with the result that the speed was increased from 16½ to 18½ knots per hour simply by a change of screws. Similarly striking results have been obtained in ships and boats of the torpedo flotilla, and in vessels of the mercantile marine. Much yet remains to be done before a satisfactory practice can be insured in choosing a suitable propeller for a ship of novel type or exceptional speed. Probably here also experiment with models of screws will come in to assist full-scale operations. Attempts in that direction have been made for many years past in the Admiralty Experimental Works, but the task is one of great delicacy and difficulty, and is far from having been completed.

Mr. Busley goes over this ground very carefully, and gives practical rules, based on experience for the most part, for fixing the sizes and pitch of screws. One of the best of these is that published by Mr. S. Barnaby and based on the extensive experiments of the Messrs. Thornycroft, whose success in the construction of exceptionally swift vessels results in part from the close attention given by them to screw-propellers. Mr. Busley has an interesting chapter on the geometry of screw-propellers; and his remarks on the most suitable materials for propellers are important.

The illustrations to this volume are numerous and well executed. The letterpress and general style of production leave nothing to be desired. It may be anticipated that the work now completed will speedily become a standard book of reference for German marine engineers.

W. H. W.

AN ARCTIC PROVINCE

An Arctic Province: Alaska and the Seal Islands. By Henry W. Elliott. Illustrated by many Drawings from Nature, and Maps. (London: Sampson Low and Co. 1886.)

MANY accounts of Alaska and of the wonderful seal-rookeries to be met with on some of the islands in its Arctic seas have been published, but none which have given in so interesting and succinct a manner the history of these far-off northern solitudes as the present volume. The author's personal knowledge of these regions, and his intimate acquaintance with the very numerous writings of others on the subject, have enabled him to write a volume that will long remain a standard one; while the illustrations from his own pencil are full of life and vigour, and add immensely to the value of the work.

The volume contains, of course, an account of the discovery, in 1741, of the Alaskan Province by Veit Bering, and of his shipwreck and sad death. The survivors spread the news of the wealth of fur and ivory that was to be found there, and soon came the rush of Russian traders. Fierce struggles took place between the individual traders and the natives, and much blood was shed, but at last a Russian American Company was established with supreme powers; and for a time, under the supervision of that very remarkable man, Governor Alexander Baranov, it flourished. Its decadence, however, proved to be as rapid as its rise; and after various vicissitudes, lasting during the first half of the present century, the district was, in 1867, acquired by the United States Government by negotiation from Russia. The name of Bering was given to the Straits connecting the Pacific with the Arctic Ocean by our Capt. Cook.

The features of the Sitkan region are treated of in a special chapter. Were it not for the damp and extensive rainfall, the climate would be endurable. A great deal of the scenery is most picturesque. The aboriginal life of the Sitkans is glanced at, but this portion of the work contains nothing very new or profound, as the author does not profess to know as much about the natural history of the human race as about that of the marine mammalia. In separate chapters, the alpine zone of Mount St. Elias, Cook's Inlet and its people, and the great Island of Kodiak, are treated of. The quest of the otter has a whole chapter devoted to it. Few ladies realise how many men are engaged in deeds of hazardous peril to obtain for them the ebony sea-otter trimming to their dainty sealskin sacques. These otters would seem to be on the eve of extirpation, so ruthlessly are they hunted and destroyed. All the world's supply comes from the North Pacific and Bering Sea. The chase and capture of the otter furnish the only employment possible for several thousands of the semi-civilised natives of Alaska, so that the destruction of this trade would be very disastrous to the hunters.

The chapter on the great Aleutian Chain tells us of the volcanic island of Oonimak, the cone-shaped crater of Shishaldin, and Oonalashka Island, with its smoking volcano of Makooshin. The chief interest of the volume centres, however, in the chapters relating to the wonderful Seal Islands, and on the modes of capture of the seals, and on their habits. The Pribylov Islands of Bering Sea were discovered just a century ago by Pribylov, the commander of a Russian sloop. He called them Subov Islands, but the Russians seem unanimously to have elected to call them after their discoverer. Sketch-maps of St. Paul and St. George are given, and there are very full and minute details of each, and of the few neighbouring rocky islets, including Walrus Island, which would appear to teem during the summer season with bird life. The history of the progress made from the earliest to the present times by the various villages on these islands is also given, and the writer alludes to the fact that the natives may be expected in the end to adopt the English rather than the Russian tongue.

The longest chapter in the volume is that devoted to the history of the habits and manners of the fur seal, which in myriads frequents these islands, and this chapter will well deserve perusal. From the economic point of view the author seems satisfied that, should the laws and regulations made by the United States Government be acted on in the future as they are now, 100,000 male seals under the age of five years and above the age of one year may be safely taken each year without the slightest injury to the regular birth-rate, or the natural increase thereof. Calculating the pups at 1,000,000 a year, of this number half are males. Of these, say one-half are lost during their first year of infancy. Owing to the polygamous habits of the males and the great age to which the adult males live, not one-fifteenth of this number is ever needed on the rookeries, and on this showing it is better that they should be killed to supply the fur trade with their skins, than that they should be allowed to live to consume millions of cod and wolf-fish.

The sea-lion (*Eumetopias stelleri*) is also a characteristic pinniped of these islands, but, having no fur, is for its naked skin valuable only to the natives. Mr. Elliott gives a graphic account of the habits of these enormous beasts, the adult males of which will measure 10 to 11 feet in length, with a girth of 8 to 9 feet around the chest and shoulders.

In the chapter on "Innuit Life and Land" a good deal of information is given as to an immense northern area, where the dwelling-houses are approached by underground passages, and where moose and reindeer abound. Still more northern wilds are described in a chapter on "Lonely Northern Wastes," while one on "Walrus and Walrus-hunting" concludes the volume. These morse are perhaps of all animals the most difficult subjects that an artist can find to reproduce from life. There are no angles or elbows to seize hold of; the outlines of the body and limbs are all rounded, free, and flowing. Some life studies of the young made by artists no doubt are good; but, until the appearance of Mr. Elliott's drawings of the fully mature animal, we had nothing in the way of portraits much better than caricatures of these strange beasts.

One interesting fact is mentioned in connection with Norton's Sound: on its shores are many low clayey bluffs, which, as they are annually undermined by the surf and chiselled by frost, fall in heavy masses on the beach, thereby exposing deposits of the bones and tusks which apparently belong to the mammoth. From time immemorial the Innuits have used this ivory for tipping their spears, lances, and arrows.

The illustrations, as we have before said, form a very prominent feature in this volume, which we commend to the reader's notice as both interesting and pleasant reading.

ANTIQUITIES OF SPAIN AND PORTUGAL

Les Ages préhistoriques de l'Espagne et du Portugal. Par M. Émile Cartailhac. Imperial 8vo, with 450 cuts and 4 plates. (Paris: Reinwald, 1886.)

ANTHROPOLOGISTS and archæologists will gladly hail this handsome volume from the pen of the editor of the "Matériaux pour l'Histoire primitive de l'Homme." It relates to two countries of the primæval antiquities of which but little is generally known, and the literature concerning whose early relics has hitherto been but scanty. It is true that we have various essays on the prehistoric antiquities of Portugal by Carlos Ribeiro, Delgado, and the Geological Commission; while those of Spain have been treated of by Signor Tubino and Dr. Vilanova y Piera, and, so far as Andalusia is concerned, by Signor Gongora y Martinez; and, as to some of the caves, by Mr. MacPherson and the late Mr. Busk. The work, however, of M. Cartailhac is far more general and comprehensive than that of any previous author. It will be well perhaps to give some sort of summary of the contents of his book.

After some preliminary considerations, he attacks the subject of the quartzite and flint flakes, which have been considered by some to prove the existence of man in Portugal in Tertiary times, but after a fair examination of the facts, not only in Portugal but in France, he regards the proofs as not sufficiently convincing, and remarks that unexceptionable traces of Tertiary man remain still to be discovered. Probably not a few of those who visited the plain of Otta on the occasion of the Prehistoric Congress at Lisbon in 1880 will agree in this verdict of M. Cartailhac.

The existence of Quaternary man in Spain has evidence in its favour of a far more satisfactory character. Sections of the remarkable valley-gravel deposits of the Manzanares at San Isidro, near Madrid, are given, as well as cuts of some of the implements there found, which, so far as form and material are concerned, might have come from the valley of the Somme. Some other implements of the same class have also been found in Portugal. Instruments both in flint and bone similar to those from the caves of the Dordogne, including needles and the peculiar barbed harpoons, have been found in caverns in the north of Spain; but at present no remains of reindeer have been found associated with them. Notwithstanding this fact, the caves would appear to be of about the same age as those of La Madelaine.

The remains of Neolithic age found within the Iberian Peninsula form the subject of the next portion of M. Cartailhac's book. Foremost among these he places the shell-mounds, which in some parts of the valley of the Tagus attain to considerable dimensions. Those at Mugem were visited by many of the members of the Prehistoric Congress, and it is somewhat remarkable that the mollusks, of the shells of which the *Kjökken möddings* principally consist, no longer are occupants of the Tagus near the mounds, but are only to be found much lower down the river, where the waters are more salt.

The principal worked flints that occur in the mounds have much the appearance of having been chisel-shaped arrow-points. Curiously enough, the mound which was thrown up as a refuse-heap by the living has been also utilised as a cemetery for the dead—intramural interments having probably not been forbidden. Some of the caves have furnished remains of pottery covered with a raised reticulated pattern, as well as objects in stone, bone, and shell. Many of them have also been the site of Neolithic interments, and the Casa da Moura has furnished one of those remarkable skulls on which trepanation has been begun but not finished. Large flat lance or javelin points of flint were found in this cave, having both faces polished after the manner of some Irish specimens. Indeed, there is a considerable resemblance in the *facies* of the flint antiquities of Portugal with what prevails in Ireland, and this somewhat corroborates the view of there having been in ancient times Iberian settlers on the shores of Hibernia. The resemblance between some of the bronze implements of the two countries is also worthy of notice. A number of ornamented pendants of slate, some of peculiar plume-like form, have also been found in the caves, the devices upon them being formed of notched and plain triangles and zigzags of almost identical character with the ornaments upon some of the Irish bronze celts.

Some imitations of stone or possibly bronze celts mounted on handles, as adzes, are very remarkable. They are carved in marble or soft stone, so that they could hardly have been used as cutting tools, but they may have had some symbolical meaning. The most interesting of the burial-places are the *Antas* or dolmens, of which a considerable number exists, some of large dimensions. In their general character they much resemble the megalithic monuments of France and Britain. Chambered barrows and *allées couvertes* are also known. In them have been found arrow-heads not unlike some of the Danish forms, with very long curved barbs and no central stem, as well as others of more simple triangular forms. In the dolmens also some of the chisel-shaped tips like those from the shell-mounds have occurred.

Traces of the old copper-mining industry of Spain have been found in the shape of large mauls of stone, with a groove or channel around them destined to receive the withe which formed the handle. The bronze swords and daggers much resemble those of Southern France and Italy, while the flat celts of bronze and of copper are like those of Ireland. The palstaves, however, or flanged hatchets, have frequently a loop on either side, instead of one only as is commonly the case in most European countries. The socketed celts have also frequently two loops, a peculiarity which is more common in parts of Russia than in other countries of Europe.

Coming down to what our author calls protohistoric times, various weapons and ornaments of the Early Iron period are figured, as well as some slabs of stone inscribed with what are apparently Phœnician letters. Of these, however, no interpretation is given. The concluding chapter is devoted to anthropological remarks, and full particulars are given of a series of skulls from some of the caves, together with photographic illustrations.

The preface to the work is from the pen of M. A. de Quatrefages, who, however, goes far in advance of M. Cartailhac in his acceptance of the discoveries of Tertiary man.

Those who are interested in the early history of mankind, and in comparative archæology in general, will do well to consult M. Cartailhac's book, in which they will find many other points of interest besides those which have been summarised in this brief and imperfect notice.

J. E.

OUR BOOK SHELF

Educational Exhibits and Conventions at the World's Industrial and Cotton Centennial Exposition, New Orleans, 1884–85. Special Report by the Bureau of Education. Part I. Catalogue of Exhibits. (Washington: Government Printing Office, 1886.)

THE extensive collection of everything connected with education which was to be made at the Exhibition held at New Orleans, and also the remarkable success of the United States Bureau in obtaining and dispersing educational information, have been referred to more than once in this journal. The Hon. John Eaton, Commissioner of Education, accepted the post of Superintendent, and the Government encouraged him to do everything in his power for the success of the undertaking; and this not unwisely, for the excellence or otherwise of the education exhibits of any locality is regarded as an attraction or warning by the most valued class of emigrants. Accordingly he made use of a visit to France, Belgium, and England to gain exhibitors, and in France he was very successful. At the Exposition he addressed large assemblies of teachers, and to himself as well as to the Bureau which he represented were awarded "Grand Diplomas of Honour" for valuable contributions. An illustrated catalogue of apparatus lent by the Bureau for experiments in the leading departments of physics is given in the Report. Among these the electrical instruments, as also a solar microscope, were particularly attractive at the Exhibition. Each State was urged to send specimens of the work, as also any objects which illustrated the growth and present condition, of its University; of its normal schools; of its schools of each grade; the work, on uniform paper, of children in every subject and standard; photographs and ground-plans of its best schools; school literature published in the State; technical work also, and both the methods and the performances of special schools, as for the blind, &c. Though not many States responded fully to this wide invitation, yet the fact that over nine thousand specimens (many of them *volumes* of school-work) were exhibited by Ohio alone, with regrets that a more complete set from all cities could not be got together, shows that a worthy response was made in some cases.

As much school *matériel* was exhibited as manufacturers could be induced by a circular from the Bureau to show gratis, and naturally the smaller articles were profusely sent in. Where specimens were deficient, as in the case of heavier furniture, heating and ventilating apparatus, &c., they were not unfrequently purchased and supplied by the Bureau, as was also a fully equipped laboratory arranged so as to economise space in schools.

Among the objects supplied by American exhibitors, were statistical charts of every educational subject. Manual training, a matter of special value in the Southern States, was carried on in the building, and the boys' products attracted particular interest. An effort was made that household industry, in its four departments of nursery, kindergarten, kitchen-garden, school of cookery, with sewing, &c., should be fully illustrated, but the first and fourth were not found practicable. A model kindergarten, in which sixteen children were being taught by means of choice objects in each important department of knowledge, instead of with books, and so furnished that it looked the brightest and pleasantest room in the building, was exhibited by the Commissioner; and kitchen-"garden" instruction, *i.e.* in domestic servants' work, was given on four afternoons a week during March and April.

Gymnastics and physical education with apparatus for exercises of various degrees of severity were shown, with lessons and illustrations several times a day. Library appliances, as well as every description of educational works, were largely exhibited in this land of the free library. Specimens of work from reformatory schools, boots, brushes, wood-work, and clothing made by boys had their place beside photographs, publications, kindergarten work, sewing and fancy work done by girls. Washington exhibited a collection of apparatus for showing the simpler scientific experiments, made by public school pupils, the illustrations of which, given in the Report, show how brain and fingers have worked together there. From the same city also was sent a miniature copy of a school recently erected there, set up as a "model" school in both senses of the word, but plans of it are not given in this Report.

One of the most important exhibitors was Prof. Ward, of Rochester, N.Y., of whose museum of natural history, though it comes under the head of commercial department, a full-page ground-plan is given. It consists of a well-balanced collection of specimens of recent stuffed and extinct restored animals; specimens of minerals found in the United States; and models of the most important geological features from all the best known parts of the globe.

An item worth notice in grammar-school, *i.e.* second-grade, education, is a collection of maps made by the boys under the master's instructions, showing countries in relief, with their natural productions denoted by little pieces of minerals, or grains of rice or corn.

A Text-book of Pathological Anatomy and Pathogenesis. By E. Ziegler. Translated and edited by Donald MacAlister, M.A., M.D. Part II. Special Pathological Anatomy, Sections IX.-XII. (London: Macmillan & Co., 1886.)

THIS, the third volume of the work, fully justifies the high opinion we expressed of its predecessors. In point of excellence of treatment, lucidity of description, general arrangement of the subject, fullness of detail, and abundance of excellent illustrations, it gives to the work as a whole a completeness and thoroughness which, we believe, have not been attained by any previous work, in English or foreign tongues. The pathology of the urinary organs is described in Section IX. (Chapters lxiv.-lxxv.); Section X. (Chapters lxxvi.-xc.) treats of the diseases of the respiratory organs, the thyroid and thymus glands; Sections XI. and XII. (Chapters xci.-ciii.) of the pathology of the central and peripheral nervous system. If amongst all that is good in the volume we had to choose what is best, we should name the chapters on the pathology of the lung and central nervous system. The classification and the detailed description of the morbid changes of these two organs are most excellent in every respect.

As in the previous volumes, so also in this, a carefully collected summary of the more recent references is given in connection with each subject. A useful index, both of the names of authors cited and of the subjects treated, concludes the volume. The illustrations are copious, representative, and well-chosen. Those illustrating the pathology of the kidney and respiratory organs are in point of printing far above the illustrations one is accustomed to see in English text-books.

As a text-book for students, and a book of reference to workers in pathological anatomy, it is unequalled.

E. KLEIN

Hours with a Three-Inch Telescope. By Capt. Wm. Noble, F.R.A.S., F.R.M.S. (London: Longmans, Green, and Co., 1886.)

THE present volume, which is to a great extent a reprint, is designed for the help and instruction of those who, possessing a small telescope, are at a loss as to how best to use it. On the whole, the book well fulfils its author's purpose. Clear, simple, straightforward, and practical, it gives just that elementary instruction in the use of a small instrument which so many require, and which has hitherto been provided for them nowhere else, and it will undoubtedly serve as a good introduction to more advanced books, such as Webb's "Celestial Objects." Occasionally a rash statement needing correction is met with—*e.g.* the footnote on p. 84—but for the most part the book has been carefully written. It is illustrated by a good map of the moon, and by over one hundred woodcuts. The latter are clear, but possess no special merit otherwise; indeed, the representations of Jupiter and Saturn are poor; but, despite a few such slight blemishes in detail, the volume cannot fail to be useful.

Lunar Science. By the Rev. Timothy Harley, F.R.A.S., Author of "Moon-Lore," &c. (London: Swan Sonnenschein, Lowrey, and Co., 1886.)

THIS little book contains a clear and interesting account of the essential facts known about the moon in ancient and modern times. Having referred, in the introduction, to some of the more general aspects of his subject, the author proceeds to discuss, in separate chapters, the moon's distance, its size, shape, substance, formation, condition, surface, and motions. In the chapter on the moon's motions, the writer has a good deal to say about the use which has been made of the moon as the measurer of time. "The etymology of the word," he says, "is full of meaning. 'Moon' and 'Month' are twins, whose parentage was Sanskrit." The truth, of course, is, not that "their parentage was Sanskrit," but that "Moon" and "Month" and the Sanskrit word "Mâs," the measurer, have the same root. As kindred words appear in several other Aryan languages, it may be assumed that the moon served as a chronometer to the Aryans before they dispersed. The Athenians began their year upon the first new moon after the summer solstice, and this year they divided into twelve months, containing alternately thirty and twenty-nine days. Each month, again, was divided into three decades. The Romans also divided their months into three parts, and, says Mr. Harley, "the first day was called *Calendæ*, from an old verb meaning 'to call out,' because a pontiff then made proclamation to the people that it was new moon. These *Calendæ* have given us our word 'calendar.'" Among the North American Indians, time is computed by moons or months, and they talk of the "beaver moon," the "buck moon," the "buffalo moon," and so on, exactly as the Greeks used to talk of the "planting moon," the "reaping moon," the "wine moon," and the like.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

Mr. Wallace on Physiological Selection

In the September issue of the *Fortnightly Review*, Mr. A. R. Wallace published an article criticising the theory of physiological selection, and subsequently published a letter in Nature conveying the substance of that criticism. Having now replied to all my critics in the current issue of the *Nineteenth Century*, I will here give the substance of my answer to Mr. Wallace.

"(1) Mr. Romanes makes a great deal of the alleged 'inutility of specific characters,' and founds upon it his extraordinary statement that, during his whole life, Darwin was mistaken in supposing his theory to be 'a theory of the origin of species,' and that all Darwinians who have believed it to be so have blindly fallen into the same error. I allege, on the contrary, that there is no proof worthy of the name that specific characters are usually useless, and I adduce a considerable series of facts tending to prove their general utility."

Now, in this matter I not only "allege," but prove, that I have upon my side Darwin himself ("Origin of Species," pp. 171, 176, 421; "Descent of Man," p. 61) and more or less "all Darwinians." Moreover, I have shown that the arguments whereby Mr. Wallace seeks to justify his own individual views are quite unworthy of their distinguished author.

"(2) In support of his view as to the swamping effects of intercrossing, Mr. Romanes objects to the assumption of Darwin, 'that the same variation occurs simultaneously in a number of individuals,' adding: 'Of course, if this assumption were granted, there would be an end of the present difficulty'; and his whole argument on this branch of the question rests on the assumption being false. I adduce evidence—copious evidence—that the supposed assumption represents a fact, which is now one of the best-established facts of natural history."

The "copious evidence" here alluded to consists merely in a reference to the well-known observations of Mr. J. A. Allen upon the kinds and degrees of individual variation exhibited by certain species of American birds. I am able to show that none of these observations have any bearing upon the "difficulty" in question; and that so far from the "assumption" in question representing "a fact which is now one of the best-established facts of natural history," even so accomplished an ornithologist as Mr. Seebohm displays so sublime an ignorance of its establishment as to affirm, in his criticism of my paper, that "it is seldom that the difficulties of natural selection from fortuitous variations have been so clearly, so impartially, but so candidly set forth." And he adds, *speaking specially of birds*, "So far as is known, no species has ever been differentiated without the aid of geographical isolation," *i.e.* without some check upon free intercrossing.

"(3) Mr. Romanes states, as the special feature of his physiological varieties, that 'they cannot escape the preserving agency of physiological selection.' He gives no particle of proof of this, while I show that, on the contrary, it is hardly possible for them to survive to a second or third generation."

The objection here is that the chances must be greatly against the "physiological complements" (or the suitably varied individuals of opposite sexes) happening to mate, and, even if they did, that their progeny should likewise do so often enough to start a permanent variety.

In answer to this objection I first of all adopt my critic's assumption, namely, that in all cases physiological selection must depend on the chance unions of physiological complements, relatively very few in number, and scattered over areas occupied by large species. Upon this assumption I agree that the sexual variation, "whenever it occurs, is almost certain to die out immediately," after which the paper proceeds as follows:—

"Granting it is shown that the union of these physiological varieties of opposite sexes is a matter of enormously rare occurrence, is it not also true that *the origin of a new species is an enormously rare event?* Not a few existing species have remained unchanged from remote geological time; the life of all species is incalculably long as compared with that of their constituent individuals; and in every generation of individuals there are, in the case of most species, millions of fertile unions. Therefore, so far as we can form any estimate on a subject where all proportion seems to fail, we may safely conclude that the ratio between the number of species which have appeared upon this earth, and the number of fertile unions between their constituent individuals, can only be represented by unity to *billions*.

"In view of this fact I am not afraid of any calculation that can be made, in order to show how many chances there are against the confluence of those conditions on the occurrence of which my theory supposes the origin of a species to depend. According to Mr. Wallace's estimate, the chances against the suitable mating of these physiological varieties 'may be any number of *thousands* to one'; so that, in view of the considerations above given, and the large number of species existing at any one time, we might conclude that Mr. Wallace supposes the birth of a new species to be an event of almost daily occurrence. Therefore, looking to what we all know are the real facts of the case, even if it were true that whenever one of these physiological varieties occurs, 'it is almost certain to die out,' this *almost* may be here quite sufficient for all that is required. Thus, upon the whole, and under my temporary acceptance of Mr. Wallace's assumptions, I confess it appears to me a somewhat feeble criticism to represent that the conditions which my theory requires for the origin of a new species are probably about as rare in their occurrence as is the result which they are supposed to produce.

"So much, then, for my first answer. My second answer simply is that from its beginning to its end this criticism is wholly in the air. Hitherto I have been considering his assumptions merely for the sake of argument. But they are not *my* assumptions; they form no part of my theory; and, therefore, I repudiate them *in toto*. The paper which Mr. Wallace is criticising clearly and repeatedly sets forth that I do *not* suppose the mating of physiological varieties to be wholly a matter of chance. Whether or not it is a matter of chance will depend on the causes which determine the variation. When these causes are of a kind which act simultaneously on many, on most, or even on all individuals occupying the same area, the element of chance is proportionally excluded. One very obvious, and probably frequent, instance of what may be termed collective variation in the reproductive system—or a variation due to a common cause acting on many individuals simultaneously—is actually quoted from my paper by Mr. Wallace himself, namely, changes in the season of flowering or of pairing, which insure that any section of a species so affected shall be fertile only within itself. Collective variation of this kind may be directly due to the incidence of some common cause, such as changed conditions of life with respect to food, climate, station, &c.; or, as in the case of bud-variation, it may be due to a single 'sport' affecting all the blossoms growing *upon the same branch*. But besides such *direct* action of a common cause, it is easy to see that natural selection, use and disuse, &c., by operating in the production of organic changes elsewhere, may not unfrequently react on the sexual system *indirectly*, and so induce the sexual change required in a number of individuals simultaneously. All the parts of an organism are so intimately tied together, and the reproductive system in particular is known to be so extraordinarily sensitive to slight changes in the conditions of life, or to slight disturbances of the organic system generally, that in their work of adapting organisms to changes of their environment all causes of an 'equilibrating' kind must be calculated more or less frequently to affect the reproductive system in the way required. . . .

"If I have succeeded in making myself intelligible, it will have been seen that Mr. Wallace's objection to my theory admits of a twofold answer. In the first place, it is impossible for him to 'show' that the origin of a species is any more frequent than it ought to be, even upon the assumption which he has imputed to me—namely, that such origin is always due to the chance mating of more or less extremely rare varieties. And, in the next place, this assumption on his part is wholly gratuitous—or rather, I should say, directly opposed both to my own statements and to all the probabilities of the case.

"From which it is easy to perceive the inevitable inference, or, if not, by stating it I will furnish a cue to future critics. *The real difficulty against my theory is precisely the opposite of that which Mr. Wallace has advanced.* This real difficulty is that the differentiation of specific types has not been of nearly so frequent occurrence as upon the theory of physiological selection we should have antecedently expected. Looking to the great sensitiveness of the reproductive system, to the many and the varied causes which affect it, to the frequency with which these causes must have been encountered under Nature, to the fact that whenever a collective variation occurs of the kind which induces physiological selection it must almost certainly leave a new species to record the fact—looking to all these things, the only real difficulty is to explain why, if physiological selection has ever acted at all, it should only have done so at such comparatively rare intervals, and therefore have produced such a comparatively small measure of result. If my critics had adopted this line of argument I should have experienced more difficulty in meeting them. But, as the case now stands, it seems enough to remark that I do not know of any way in which an adverse criticism admits of being more thoroughly exploded, than by showing that the difficulty which it undertakes to present is the precise opposite of the one with which an author is in his own mind, and at that very time, contending.

"Seeing how remarkable has been the misunderstanding displayed by such competent readers as Mr. Wallace and Mr. Seebohm—a misunderstanding on which they both found their only objection to my theory—I should have been compelled to suppose that my paper failed in clearness of expression, were it not that (as above shown) they have disregarded the literal construction of my sentences. Nevertheless, it is probable enough that I may not have sufficiently guarded against a misunderstanding which it never occurred to me that any one was likely to make. For I supposed that all readers would have perceived at least that the main feature of the theory is what my paper states it to be—namely, that sterility with parent forms is one of the *conditions*, and not always one of the *results*, of specific differentiation. But, if so, is it not evident that all causes which induce sterility with parent forms are comprised by the theory, whether these causes happen to affect a few individuals sporadically, a number of individuals simultaneously, or even the majority of an entire species?"

George J. Romanes

Meteor of December 28, 1886

The meteor referred to by your correspondent "J. M. H." (Nature, January 6, p. 224) was also observed at Bristol at 10h. 28m. The path was from $95° + 9\frac{1}{2}°$ to $106\frac{1}{2}° - 6°$. A train of sparks was thrown off from the nucleus as it slowly fell.

Comparing the apparent course of the meteor as recorded at Sidmouth and Bristol, it is evident that its radiant-point was at about $77° + 30°$, near β Tauri. It belonged to a shower which appears to have a very extended duration, and has been specially referred to, with diagrams, in Nature, vol. xxxi. p. 463.

This recent meteor affords unmistakable proof that the radiant near β Tauri continues active until the end of the year. The relative paths at Sidmouth and Bristol show that the meteor was about 97 statute miles high at its first appearance over a point in the English Channel some 28 miles off the Isle of Wight. Moving with a very slight inclination west of north, it disappeared 10 miles south-west of Niton, Isle of Wight, when 39 miles high. It traversed a path of 62 miles at an inclination of 69° to the earth's surface.

The duration of the meteor was about three seconds, so that its velocity appears to have exceeded 20 miles per second, which is greater than that of a body moving in a parabola, though the difference may quite possibly have been induced by observational errors. As regards visible effect, the meteor can lay no claim to the dignity of a fire-ball, but it is one of considerable interest as belonging to the remarkable display of β Taurids.

Bristol, January 7 W. F. Denning

The Production of Ozone

I shall be much obliged if you can inform me through your paper—

(1) What apparatus would be most conveniently and easily worked by ordinary persons for the production of ozone in a room? I have tried a four-cell Smee's battery with a Siemens' ozone tube. This produces the required quantity of ozone, and works well in the hands of people used to scientific apparatus, but the general manipulation (especially as regards keeping the battery in working order) is above most people.

(2) Is there any battery you know that would give good results and be easily worked by people wholly unused to scientific apparatus (domestic servants for instance)? The quantity required is what would keep the air of an ordinary sitting-room, say $18 \times 16 \times 11$ feet so charged, that ozone would be always just sensible to the smell.

I see by the advertisements of the hotels in the Engadine, that the air in their corridors is kept constantly ozonised. (3) Could they adapt their electric light dynamos for this purpose? (4) If so, how?

I may say I have no "trade purpose" in making these queries. I am a sufferer from phthisis, and find relief in the inhalation of ozone, but I want an apparatus that I could leave to my servants to manage. W. H.

"Brading," Madeira Road, Bournemouth

JOHN ARTHUR PHILLIPS, F.R.S.

By the sudden death of this chemist and metallurgist on the 5th inst. geology loses one of its ablest leaders in a department where the labourers are not very numerous here, and at the same time one of the kindliest and most helpful among the students of science. Mr. Phillips was born in Cornwall, and among the metalliferous rocks of that county began the scientific researches which he has since prosecuted with so much success. Having early shown his taste for mining and metallurgy, he was sent to obtain his training in these subjects at the École des Mines of Paris. As far back as 1841 he began to contribute papers to the scientific journals. His early essays were almost wholly devoted to chemical and metallurgical subjects. His studies among the Californian goldfields, however, led him to investigate wider questions in physical geology. By degrees he turned into the domain of petrography, and for the last sixteen years it has been mainly in that branch of science that his original researches have been carried on. His papers on the eruptive rocks of the south-west of England are admirable illustrations of the value of the union of chemical and mineralogical qualifications in petrographical inquiry. Most of his time during the last two or three years had been devoted to the production of large and important treatises. Of these his volume on "Ore Deposits," published in 1884, has taken its place as a standard English work of reference. At the time of his death he was busy with the preparation of a new edition and expansion of a work on "Metallurgy," which he had published when still a young man. In this task he had associated Mr. Bauerman with himself, in whose competent hands the volume is sure to see the light in a form worthy of its author's reputation. Those who were personally acquainted with Mr. Phillips, while they lament the loss to science which his sudden death has inflicted, mourn still more the extinction of a life of singular simplicity, earnestness, and kindliness. He was a large-hearted and open-handed man, fond of taking every chance that came in his way of doing a good deed and helping every one to whom his help could be of service.

BOTANICAL FEDERATION IN THE WEST INDIES

In the nearest of our tropical colonial possessions, which comprise the group of islands generally known as the West Indies, the dominant industry for the last hundred years has been that of the sugar-cane. Sugar and rum are indissolubly connected with these islands, and, under the circumstances which existed fifty years ago, there is no doubt that lowlands in the West Indies were better suited for the remunerative culture and growth of the sugar-cane than any other plant. Owing to a variety of causes, among which the abolition of slavery and the extension of sugar plantations in other lands are the chief, sugar-growing in the West Indies has suffered numerous reverses of fortune. Latterly, the difficulties of planters have been greatly increased by the improved production of beet-sugar in Europe.

The chief sugar islands at present are Barbados, Antigua, St. Vincent, Trinidad, St. Lucia, and Tobago. At Jamaica, sugar and rum are still the staple industries, and form 39 per cent. of the exports, the balance being made up by other industries, such as coffee, fruit, and dye-woods. At Trinidad cacao is largely grown, and the export value of this article is nearly two-thirds that of sugar. Grenada, once a large sugar-growing colony, is now almost entirely devoted to cacao. Montserrat is becoming noted for its lime plantations, and exports of lime-juice; while Dominica exports concentrated lime-juice, cacao, cocoanuts, and tropical fruits. The Bahamas have a large tropical fruit trade with America, supplemented by the export of sponges, to the value of £60,000 annually. In spite of these smaller industries, however, there is no doubt that the chief business of the West Indies is still that of sugar. A capital of something like fifty millions sterling is invested in it, and the people are naturally reluctant to relinquish an industry which has, in the course of a century, become thoroughly established, and which is familiar in its details to all classes of the community. But, after all, it is impossible to overcome the logic of facts: and it is admitted on all sides that sugar, under present circumstances, can with difficulty be grown and manufactured to pay a profit. Hence it is not surprising that there is a strong desire to enter upon other cultivations; and it is well for the future prosperity of the West Indies that this should be so. The depression in the past and the comparative poverty of the present are no doubt due to the exclusive cultivation of one plant; for under such circumstances, when the sugar-market is depressed, everything is depressed. If improvements in cultivation were adopted, and if such high scientific skill as is applied to the manufacture of beet-sugar were applied to the manufacture of cane-sugar, it is the opinion of many that the planters would again become prosperous. But something more is necessary. With the exception of two islands in the whole group—namely, Antigua and Barbados—it is estimated that more than one-half of the actual surface of the West Indian Islands is suitable for other cultivations than sugar-cane. This being so, the people injure their best interests by neglecting the resources at their disposal.

In purely sugar islands, such as Barbados and Antigua, permanent improvement is to be sought in more economic and improved systems of cultivation, added to which there should be a concentration of all purely manufacturing processes under what is known as the *Usine* system. This latter system is already in existence at Trinidad, St. Lucia, British Guiana, and in the French island of Martinique; and it is proved beyond question that where the manufacture of sugar is treated as a highly specialised industry, finer and better qualities are produced, and the expenses are considerably diminished. Planters are therefore recommended to confine themselves as much as possible to the cultural operations of a sugar estate. Under such a division of labour there would follow a more careful trial of different varieties of the sugar-cane, adapted to the different soils, a more scientific application of special manures, and such general regulation of all cultural operations as would produce canes of the highest saccharine richness. In Barbados, Trinidad, and Jamaica, there are already Government analytical chemists, who are qualified to give valuable information to planters as regards soils and manures; and from a report recently prepared at Barbados by Prof. Harrison it is evident that much good would result from a larger utilisation of chemical knowledge as applied to sugar cultivation, both in the interest of the individual and of the general community.

During the last five or six years efforts have been made to increase the efficiency of West Indian industries by a wider and more general application of scientific methods not only to the sugar-cane but to all other plants which may be found suitable to the circumstances of the several islands. Hitherto two botanical establishments have been maintained for the West Indies—one at Jamaica and the other at Trinidad. From these centres, but especially from that of Jamaica, economic plants and information by means of annual reports and other publications have been regularly furnished, and such agencies have greatly assisted in enlarging the scope of experimental culture.

In the Report of the Royal (West Indian Finance) Commission, appointed in 1883, it was stated that there was a growing inclination on the part of the planters in other West Indian colonies to apply for seeds and plants to the Botanical Establishment in Jamaica, which could supply each island with what it required in the most economical manner. Sir Joseph Hooker, commenting on this report, expressed the opinion that there could be no doubt that the future prosperity of the West Indies would be largely affected by the extension to other islands, unprovided with any kind of botanical establishment, of the operations so successfully pursued in Jamaica. And it was suggested by Mr. Thiselton Dyer that, in addition to the distribution of plants, there might be organised a regular system of botanical bulletins, containing practical hints as to the treatment of economic plants, and the conditions under which they might be best utilised as objects of remunerative industry.

At the instance of the Secretary of State for the Colonies, it was ultimately decided that the whole of the West India Islands should be asked to co-operate in a systematic endeavour to promote and extend the cultivation of economic plants, and thus to develop more fully than heretofore their natural resources. This proposition was duly laid before the Governments of Barbados, the two groups of the Leeward and Windward Islands, and the colony of British Honduras. On account of the want of direct and regular communication, it was found impossible to include the Bahamas, while British Guiana is already supplied with its own botanic garden. The conditions on which the islands lying within the West India group were asked to join in this industrial federation were, first, the provision of an annual grant for the maintenance of a local station to discharge the functions of a scientific outpost and a nursery; and secondly, the contribution of small sums towards the support of operations at the central establishment. These small sums were intended to cover the special expenses incurred in behalf of each island in maintaining a depot for seeds and plants, and to pay the cost of publishing the botanical bulletins, which were intended to form an important feature in the scheme. The Legislative Council of Jamaica has recently expressed its willingness to give effect to the principle of the scheme as regards making the Botanical Establishment in that colony one of the central points of action; and it is anticipated that, while granting valuable aid to the smaller islands, Jamaica itself will derive, both directly and indirectly, considerable benefit from such vigorous and systematic working as would naturally arise in its own area, as well as from a larger interchange of plants and seeds with the neighbouring islands.

It is hardly necessary to observe that, in reply to the Secretary of State's despatch, the smaller islands were not slow to express their desire to be included in the scheme, and steps were taken in several to give effect to this desire by the establishment of local stations. Barbados was fortunate in possessing favourable means for starting a botanical station in connection with the Boys' Reformatory at Dods, where land was already under experimental cultivation in canes and in food-plants suitable to the district. This station is now at work, under a committee whose business is to supervise operations, and to communicate directly with the central establishment.

Grenada, which is in a fairly prosperous condition, has enlarged the original idea of a botanic station by making provision for a small botanic garden, which is now in course of being laid out under the charge of a trained superintendent (originally from Kew, but with Jamaica experience) at the Paddock, within easy reach of the town of St. George. At St. Vincent the proposal to utilise the old botanic garden of the colony as a botanical station has been adopted, but the provision at present made is insufficient for the purpose, and will require to be slightly increased.

St. Lucia, to the north-west of Barbados, has shown a spirit of commendable energy in taking up the idea, and has given practical effect to it through the operations of its well-organised agricultural society. An experienced curator, also from Jamaica, has recently been appointed to the charge of the station, and good results are anticipated. At Dominica the botanical station has not yet assumed a practical form owing to the depressed state of the finances; but there is little doubt that ultimately such a station will be established, and the resources of this fertile island more largely developed.

Further north, Antigua, more especially concerned in the cultivation of the sugar-cane, has joined the scheme, and apparently is only waiting the completion of final arrangements at the central establishment. British Honduras, which has already benefited by its intercourse with the Botanical Establishment in Jamaica, has the site for a station, and a managing body has been appointed to begin operations at an early date.

To give a certain cohesion and uniformity of action to these several agencies, it was thought very desirable that a visit should be made to the islands concerned by the head of the Jamaica Department. This was accomplished in the early part of last year by the writer of these notes, who was happy to devote a short holiday, on retirement from Jamaica, in visiting the islands at his own expense.

During this visit sites for stations were examined and discussed, and suggestions made for their working on the lines best suited to local circumstances. As a practical instance of the feasibility of a botanical federation of the West Indies, it may be mentioned that recently an inquiry has been made, by general consent of the local Legislatures, into the condition of the indigenous forest growths of these islands, by Mr. E. D. M. Hooper, of the Madras Forest Department.

The Reports on Jamaica and St. Vincent are already published, and they are of such a practical and useful character that they cannot fail to have an appreciable effect upon the treatment and management of the forests both as reserves of timber to supply future wants, and as a means of maintaining a due humidity of climate and protecting the sources of springs and rivers. These Forest Reports, when completed, will add greatly to our knowledge of West Indian timbers, their nature, extent, and distribution; and they will also afford for the first time in history the actual economic and meteorological conditions of the interior of several islands beyond the confines of the present areas under cultivation.

In many instances the natural forest trees, as at Barbados, the Virgin Islands, and some of the islands of the Grenadines, have been nearly exterminated; those once very common, and represented largely in collections of botanical travellers of the last century, are now almost unknown. If the botanical stations are carried on with due regard to the industrial wants of the community, and are not allowed to degenerate into mere nurseries for ornamental plants, they will indirectly do much to enlarge knowledge as regards local floras, and bring to light many indigenous plants likely to prove useful on account of such medicinal and economic properties as they may possess. In the year 1824 it was laid down as one of the objects of the then Botanical Garden, at Jamaica, that it should devote attention "to the investigation of many unknown native plants of the island, which, from the properties of those already known, it is reasonable to infer would prove highly beneficial in augmenting internal resources by supplying various articles either for food, for medicine, or for manufacture, . . . by means of which great commercial advantages might be obtained; among others, the various vegetable dyes claim particular attention, as promising a fruitful field of discovery." As indicating the direct bearing which this one field of inquiry (vegetable dyes) among many others had upon the future of Jamaica, it is interesting to note that while no dye-woods whatever were exported from the island in 1824, a small trade of the value of 1859*l.* was started in 1833, which since that time has steadily increased, until now it has assumed relatively large dimensions. The exports of dye-woods in 1870 reached a gross value of 112,313*l.* ("Jamaica Handbook," 1884-85, p. 375).

Similar results in more recent times have attended the increased attention given to the cultivation of fruits that had been neglected in Jamaica. The export of these in 1875 amounted to 14,912*l.*, in 1884 the total value had increased to 273,534*l.*

Results such as these, although obviously of a special character, justify any attempt that may be made to improve the circumstances of the West India Islands; and they afford also a striking instance of what is capable of being accomplished in these islands when careful investigation and judicious and enterprising effort are made to fit local circumstances to the demands of the outer world.

As regards the carrying out of a scheme of local enterprise in the West Indies, it may be mentioned that the recent appointment of Mr. William Fawcett, a highly-qualified botanist, to the post of Director of the Botanical Department in Jamaica, and the transfer of Mr. Hart, late senior Superintendent at Jamaica, to the post of head of the Botanic Garden at Trinidad, appear to offer every hope of success to a botanical federation of the West India Islands. Jamaica and Trinidad, as the two foci of operations, could very well group round them the lesser islands, and the full realisation of such a scheme as is here indicated only requires such working out of details as may well take place at an early period.

It is important, however, to bear in mind that the success of the Jamaica Botanical Department, which has acted for several years as the centre of botanical and economical operations in the West Indies, has been in a great measure due to the valuable suggestions and the moral and material support which for many years it has received from Kew. It was from Sir William Hooker that Jamaica received its first supplies of seed of the several species of Cinchona, which have laid the foundation of the only English Cinchona enterprise in the New World. It was from his illustrious son and successor at Kew, Sir Joseph Hooker, that Jamaica received its tea plants and seeds, india-rubber plants, coca plants, fibre plants, and regular and large supplies of all the economic and medicinal plants which have flowed through Kew for distribution to various portions of the British Empire. Few can realise the eminent services which have been rendered by Kew in this direction, both by its correspondence and contributions, but there is every reason to believe that the results will ultimately be apparent in the greater prosperity of the inhabitants of the West Indies, and in the larger development of their rich and varied resources.

D. MORRIS

ART AND SCIENCE IN A NEW LIGHT

MR. BRETT is an artist of reputation and of remarkable industry. His pictures are popular, and meet with appreciative purchasers. He is enrolled among the Associates of the Royal Academy, and no doubt looks forward to be in due time raised to the dignity of Academician. At the request of the Fine Art Society he has this winter allowed a series of about fifty sketches painted by him on the west coast of Scotland last summer to be exhibited in the New Bond Street rooms. These sketches show that he has recently spent a long holiday among some of the most delightful scenery in the British Isles. As a man who has evidently got on in the world, looking back upon a distinguished past and forward to perhaps a still more distinguished future, he might reasonably be expected to smile pleasantly on the world that has used him so well. If the keen eyes that stand him in such good stead in landscape-painting reveal to him the weaknesses and frailties of his fellow-men, one might at least anticipate that they would wink hard at these shortcomings and rather turn to the good side of men and of things. But apparently Mr. Brett sees only too vividly what he conceives to be the impostures and ignorances around him, and his soul is stirred within him at the sight. The exhibition of his last year's sketches has furnished him with the occasion for discharging the vials of a wrath which, like that of Tam o' Shanter's wife, he must have been nursing for a long while to keep it so warm.

The Exhibition (now closed) was illustrated by a pamphlet, which on the title-page is described as "An Explanatory Essay," and on the first page is more emphatically designated as "The Commentaries." Mr. Brett, apparently with some presentiment that this literary effort of his might not meet with the same kind reception that attends his pictorial labours, stipulated expressly, as he tells us in a "Prefatory Note," that his paper should be published exactly as it left his hands. We cannot therefore plead for him that his essay was hurriedly thrown off in a fit of ill-temper. He ostentatiously goes out of his way to accept the responsibility of its matter and its style. A description of each picture, from the artist's point of view, with a running commentary on his method of working, the difficulties in Nature to be overcome, and his way of grappling with them, would have been interesting to the general public and valuable to artists and students of art. He seems to have started with the idea of writing some such commentary. But by the time he gets to the second page he catches sight of the red rags of imposture and ignorance, and without more ado rushes madly at them. The first victims of his fury are press critics of art. Nothing is too contemptuous to be said of them. Mr. Brett looks on them as a set of ignorant charlatans, too idle to work, too proud to beg, but who are glad to earn the slender pay allowed to them by careless editors. Some wretched scribbler had pronounced his work to be "laborious," which we would have thought rather a complimentary epithet; but Mr. Brett cannot forgive it. The writer who used it he stigmatises as a "bell-wether," and those who blindly followed his lead are described as "enlightened tom-tom players, who have gone on sounding the same note for a quarter of a century or more."

After this onslaught the painter tries to find his way back to where he was, and for a little while the reader begins seriously to entertain the hope that the promised commentary is coming. But the author gets upon the subject of clouds, and instantly a bigger bunch of red rags looms in front of him. Down goes the head, and with one triumphant howl of derision the infuriated writer rushes at scientific men in general, and the Royal Society in particular. After this second outburst he hardly calms down again till the end of the performance. No sooner does he turn from the treatment of the clouds to the ground beneath us than geological theories in all their hideous deformity and crass ignorance stare him in the face. The text is not roomy enough to contain all that he has to say about the misdoings of the geologists, so that he has to overflow into a footnote. Next comes the turn of those misguided astronomers who have led mankind wrong about the moon and the planet Mars.

One is tempted to ask what is the meaning of all this sound and fury. What relation has it to the pictures it is meant to preface? What object can the writer have had in indulging in it? Men of science are, no doubt, often wrong. But at least they take the trouble to try to be right. Their greatest aim is to get at the truth, and they welcome whatever will lead them nearer to that goal. They will even willingly learn from Mr. Brett if he has anything to teach them, though he laughs them to scorn, and derides them as "scientific Johnnies," "lovers of jargon," makers of "real gibberish," by whom various "forms of silliness are palmed off as science disguised in Greek or Latin." If the meteorologist turns for suggestions to Mr. Brett's essay, he there learns that "the fundamental phenomena of evaporation have always been misrepresented," and that he and his gaping fellow-students of Nature will learn more about clouds from the pictures of a well-known landscape-painter "than from all the Transactions of the Royal Society put together." If the geologist inquires what Mr. Brett has to say for his consideration regarding the "laws of the rocks," he is told that water is a "recent formation," that upheaval is a "childish conception," and that geologists "ignore the moon." If the astronomer in turn asks what the author of "The Commentaries" has to say in his department of knowledge, he is informed that Mr. Brett defies him "to point out a single instance of a volcano or a volcanic crater in the whole disc" of the moon. The "jargon" and "real gibberish" of modern science not only afflict the artist's own soul, but they disturb the peace of his family. "One professor the other day," he indignantly exclaims, "learnedly instructed my boy that aqueous vapour was formed by evaporation!" Hapless youth! Let us hope that his father has found time to instruct him in "the fundamental phenomena of evaporation."

After such a tirade against scientific men, one might suppose that Mr. Brett would be disposed rather to avoid them, or at least not to show himself ostentatiously in their company. And yet the reader will be amused to discover him, in the midst of these rabid denunciations, contriving to find room for a statement that he himself has written a scientific paper which has been published in a scientific journal, and that this important fact may not be missed, he quotes the paper in a footnote! Is Saul also among the prophets? There would be something pathetic, were it not so ludicrous, to see the proud paternal way in which the artist brings forward his feeble little scientific bantling. We should not be surprised if he thought more of it than of some of the pictures that have made his fame. His contempt for "lovers of jargon" and "real gibberish" is apparently equalled by his profound satisfaction with his own achievements. Not content with indicating the artistic value of his work, he claims that, "if these sketches have any distinct peculiarity worthy of notice, it is that they are optically correct, or at least are intended to be so, and that intention, strange to say, is new in pictorial art"! It would be interesting to hear the painter's defence of the "optical correctness" of some of the pictures. Did he ever see, for instance, a castle standing as he has depicted one in No. 22? Of his peculiar greens and blues we need not speak. They are part of his "confirmed mannerism," to use his own phrase, and are characteristic of his canvas, no matter under what skies and among what seas and rocks he may paint.

The pamphlet to which reference has been made in this article would not, of course, have been noticed here but for the name of its author. Science owes much to art, as art in turn lies under many obligations to science, and it should be the aim of each to help forward the other. That a man of Mr. Brett's artistic attainments should have gone out of his way to pen this "form of silliness" is to be regretted chiefly for his own sake. He has injured his reputation for common-sense, and this even a great genius cannot afford to do.

THE NATIONAL SCIENCE COLLECTIONS

THE following Report of a Committee appointed by the Government to consider the housing of the objects illustrating the physical sciences belonging to the nation has recently been printed and circulated. The Committee consisted of Sir F. Bramwell (Chairman), Lord Lingen, Colonel Donnelly, C.B., and Mr. Mitford, C.B.:—

1. We, the Committee appointed by the Lords Commissioners of Her Majesty's Treasury to consider certain questions that have arisen in regard to the Scientific and Technical Collections at South Kensington, now beg leave to present to their Lordships our Report thereon.

2. The appointment of the Committee included the name of Sir Francis Sandford, K.C.B.; but this gentleman, in consequence of the pressure of other public business, has been unable to attend any of our meetings, and he has authorised the other members to proceed with the inquiry, and to report, in his absence.

3. Our instructions were conveyed in a letter, dated January 14, 1884, and a memorandum accompanying it, from Lord Richard Grosvenor to the Chairman, and were to the following effect:—

"It will be the duty of the Committee (1) to consider and report upon the scope of the Scientific and Technical Collections, including the Patent Museum, and the space required for them, immediately and prospectively; (2) to suggest plans for housing these Collections in the existing galleries to the south of the Horticultural Gardens, or in new galleries to be built upon their site, and the adjacent ground now the property of the Government."

PRESENT DISPOSAL OF THE SCIENCE COLLECTIONS

4. Before we enter on the consideration of these questions, it will be convenient to explain how the collections are at present housed.

They are contained in five buildings which are shown on the accompanying Plan, Drawing No. I., and are marked A, B, C, D, E; whereof A, B, C, and D are on the west, and E is on the east side of Exhibition Road.

The buildings A, B, E, coloured yellow on the plan, and their sites, are the freehold property of the Government; the buildings C, D, coloured blue, and their sites, are the property of the Royal Commissioners of 1851, from whom they are rented by the Government.

5. C is a block forming the centre portion of the galleries to the south of the Horticultural Gardens. It is about 292 feet long, 55 feet wide, and two stories high. It contains 22,000 square feet of available floor-space.

This building is the property of the Royal Commissioners of 1851, and is at present leased from them by the Government for 1500*l.* per annum. The lease terminates in 1890 or 1897, with a power up to January 1888 of purchase for the sum of 30,000*l.*, or, at the option of the Commissioners, for such sum, not exceeding 35,000*l.*, as may be fixed by the President of the Institute of British Architects.

6. A and B are the southern wing-galleries, the former on the east, and the latter on the west side of the central block C, and having short returns or spurs, A′ and B′, to the northward, at their external ends.

These wing-galleries extend about 280 feet in length on each side of the central block; they are about 26 feet wide, and two stories high.

The returns at each end are each 72 feet long, and one story high.

The whole contain about 29,500 square feet of available floor-space.

These buildings, and their sites, are the property of the Government.

7. D is a building known by the name of the Western Gallery. It is 600 feet long, 33 feet wide, and two stories high. It contains about 36,560 square feet of available floor-space.

This building is the property of the Royal Commissioners of 1851, and is at present rented from them by the Government for the sum of 2000*l.* per annum. We believe, however, it is desired to give up the tenancy if possible.

8. E is a temporary building one story high, abutting on the south end of the permanent buildings of the Museum on the eastern side of the Exhibition Road. It contains 7500 square feet of available floor-space.

It is the property of the Government, but we understand it must be pulled down before long, to make way for more permanent erections.

9. These buildings are not altogether devoted to the Science collections.
